5. A Simple Means of Lessening or Eliminating Alimentary Toxaemia.—Chetham-Strode and Benjafield, assuming, in line with the teaching of Metchnikoff and his school, that a lactic-acid fermentation in the large intestine is the condition to be aimed at, hold that the problem reduces itself to one of simple chemistry. We know that lactic acid is produced in milk by the fermentation of the lactose by bacteria. We have in the large intestine numerous bacteria capable of effecting this. We have, therefore, to find some means of supplying the necessary lactose. Carbohydrates administered by the mouth in the usual digestible form will not supply this ingredient, as they are broken up and absorbed during their passage through the stomach and small intestine. Thus the carbohydrate must be supplied in some form in which it can resist the action in part, at least, of the gastro-intestinal ferments. The simplest means of overcoming this difficulty, and the one adopted by the writers in their practice, is to administer the carbohydrates in the form of coarse, uncrushed oatmeal. This may be taken raw or cooked sufficiently to soften the outside of the grain, only leaving behind a hard core. The result is that the partially digested grain reaches the large intestine in the form of carbohydrate. The centre of the grain is composed of unaltered starch, while the outer layers, which have been subjected to the digestive action of the juices of the mouth, stomach, and small intestine, are composed of simpler molecules, the disaccharides, and hexoses. Both these latter can be rapidly converted into lactic acid and CO_2 by a suitable bacterial flora. The feces of the average individual are neutral or alkaline to litmus, and, from what has been said, it would appear that the production of a lactic-acid fermentation is quite a simple matter. This takes place in many cases, more especially when dealing with the young, but there remain quite a large number of individuals whose excreta do not at all readily become acid. The causes which may prevent the acid fermentation may be grouped under the following headings: (1) stasis; (2) presence of unsuitable organisms in the fecal flora; (3) absence of essential organisms in the fecal flora; (4) an unsuitable dietary. These categories are discussed and five typical cases cited.

6. The Paratyphoid B. Group.—Harry Schütze, referring to the contention, on the one hand,

that it is possible, by means of the absorption test, to differentiate between Aertrycke and paratyphoid B organisms, and the attempts, on the other hand, of various workers to prove the invalidity of the differentiation, still others advocating the use of certain cultural tests to supplement the serological characterization of the two groups, details his own investigations in this connection. During the examination of a number of strains he came to the conclusion that not only, as is becoming universally recognized, is it possible to differentiate, by the investigation of their respective absorptive characters, and Aertrycke bacillus from a paratyphoid B, but to subdivide, by means of the same test, the Aertrycke organisms into a number of types. From his investigations he draws the following conclusions: 1. By means of Castellani's absorption test it has been possible to divide the "Aertrycke" group of organisms into a number of types, of which one (Mutton type) is by far the most largely represented, 24 organisms from 16 foci belonging to this type out of 46 strains from 28 foci. 2. As the various "Aertrycke" types serologically agree with, and differ from, one another in the same way as each agrees with, and differs from, paratyphosus B, the "Aertryckes" and paratyphoid B have been placed together in one group, of which they thus represent a series of types. There is some evidence for concluding that just as paratyphosus B may occasionally produce acute gastro-interitis in man, so may a typically Aertrycke-like bacillus occasion continued fever resembling enteric. Thus there seems no good reason for separating one para. B type of from a series of Aertrycke or otherwise named types, and it is suggested as simple and justifiable that paratyphosus B be used as species-name for the whole group, the particular variety being indicated by the addition of a type-name, such as Schottmüller, Mutton, Hirschfield, and so on. 3. Reasons for regarding as a member of the paratyphosus B group that organism which in the East is apparently of particular importance, and has been called by some workers paratyphosus C, are here set forth, and the question of nomenclature is considered.

1. A Clinical Lecture on the Surgical Aspects of Spinal Tumours.—Percy Sargent, from a study of fifteen cases of encapsuled intrathecal extramedullary tumors, and twelve cases of tumor causing cord symptoms, other than those of the first class, holds that the chief lesson to be learned from the study is that early exploratory operation should be more frequently undertaken. Neither should a clear history of syphilis nor the existence of a positive Wassermann reaction be considered as a contraindication for operation should improvement not rapidly follow the administration of antisyphilitic remedies. For persons with active syphilis may suffer from spinal neoplasms (three out of fifteen of his cases of simple extramedullary tumor), while a constriction of the cord by fibrosis following gummatous meningitis, incapable of being influenced by drugs, may be successfully dealt with by operation.

3. A Traumatic Neurosis in a Case of Syphilis.—James A. Wynn reports a case studied at the Robert W. Long Hospital, Indianapolis, which illustrates the possibility of the existence of a traumatic neurosis masked by the symptoms of other existing diseases. The conclusions drawn from the history of this case are that the existence of a four plus Wassermann should not blind one to the fact that an entirely independent nervous lesion can coexist with syphilis. In this case, the faulty verdicts of two hospitals did real harm in focusing the patient's attention on a wrong conception of his condition, and the cure of his neurosis was impeded by his well established belief that he had incipient taboparesis. The subsequent history of this patient bears out the opinion that the entire syndrome in his case was a neurosis, amenable to psychotherapeutic measures.

1. The Status of Amebic Dysentery with Special Reference to Diagnosis and Treatment.—Randolph Lyons states that the diagnosis of amebic dysentery and of the carrier state is fundamentally dependent upon the finding and identification of the organism in the stool. For the detection of the active or vegetative endamebae, a stool obtained after the administration of a saline cathartic is best suited; cysts, on the other hand, are more readily found in the more solid stool. Where the identification of a species is in doubt, methods for testing its pathogenicity must be employed. For this purpose kittens have been found the most susceptible animal. This method, however, has been made very little use of except in experimental work. The proctoscoscope or sigmoidoscope offers a valuable means of diagnosing amebic dysentery, as ulcers thus noted may appear so typical as to be pathognomonic. Furthermore, in this manner material for examination may be obtained directly from the base of an ulcer by the use of a long applicator. Not only does the proctoscope aid in diagnosis, but also in determining the severity of the disease and in gauging the progress of treatment. Roentgenological findings may also be of assistance in making a diagnosis of amebic dysentery. Attention is directed to the fact that Roentgen findings in the North may be of greater differential diagnostic value than in the South. The subject requires further study, especially in the South, before the diagnostic value of Roentgenological findings can be estimated. The writer hesitates to record the therapeutic test as a method of diagnosis; nevertheless there will occasionally be a case where, after conscientious study of all the data obtainable, the diagnosis still remains uncertain. In such cases it is only fair to the patient that he be given the benefit of any doubt and treated accordingly. The treatment of amebic dysentery is summarized in the statement that ipecac and its alkaloids are still the sheet-anchor. The tendency of the times is to administer a combination form of treatment—that is to say, emetine hydrochloride is given hypodermatically in conjunction with the oral administration of either emetine, hydrochloride, powdered ipecac or emetine-bismuth-iodide. Occasionally some other drug may be administered by mouth as Chaparro or bismuth. There is reason to believe, in the writer's opinion, that this form of treatment is a distinct advance in the therapy of amebic dysentery, and that by its use relapses will be markedly diminished. It has met with notable success in the treatment of carriers.

3. Mistakes and Puzzles in Blood Examinations.—S. R. Klein calls attention to various mistakes that may cloud the issue in reporting blood examinations. Parasitelike bodies, for example, may gain access to films from the alimentary tract. The skin, and more especially the hairy hides in animals, and the feathers of birds, often yield their quota, and some very curious looking organisms may thus be added to a blood smear. What, he asks, will guide one in distinguishing a stained yeast cell from a blood parasite? Another kind of fallacy may happen through carelessness in the handling of slides, pipettes or other materials used in making the blood examinations. Mistakes may be made in distinguishing a vacuole from a young malarial parasite, piropasm or a spirochaetal inclusion. There are thousands and thousands of mistakes about granules, granulations, chains, dumbbells, droplets and ilament phenomena. Haemoconia, free flagella, platelets, alterations in red cells, corps en assaire, Howell, jelly bodies, centrasomes, degenerations in leucocytes, bodies in the extranuclear protoplasm of certain mononuclears, spherical plasmocytes, free spores, and thousands of other unidentified parasites may have a tremendous influence upon changing the diagnosis from a laboratory standpoint.

2. Constitutional Symptoms and Focal Infections of the Genito-Urinary Tract.—David W. MacKenzie holds that the importance of focal sepsis in its relation to the genito-urinary tract entitles it to a prominent position in the minds of internists, general surgeons and the various specialists. Among the numerous septic infections involving the genito-urinary system, which, untreated, are prone to lead to constitutional involvement, may be mentioned acute suppurative nephritis, pyelitis, pyelonephitis, pyonephrosis with or without calculus, tuberculosis of the kidney, renal and perirenal abscesses, ureteritis, pyo-ureter with or without calculus, cystitis, especially associated with urinary obstruction, seminal vesiculitis, and epididymitis. The various conditions are discussed and case reports given.

Revue Médicale de la Suisse Romande.

October, 1919, xxxix, 10.

The Pandemic of 1918.—Krafft finds that we know but few things about the late great epidemic. The bronchial secretions during the period surely spread the disease or at least are highly virulent to monkeys by conjunctival or intranasal inoculation. The contagious principle goes through a filter. It does not render human blood virulent but the disease can be transmitted by subcutaneous injection. This is about all we know and our knowledge is based on a concordance of results—finds by the leading experimental pathologists. When the pestilence first appeared in June the author caused the fifty attendants under his administration to gargle thoroughly several times daily with potassium permanganate and for several weeks no case developed. Finally in July two attendants fell ill and later confessed that they had omitted the precaution. In one hospital the attendants and employés to the number of 59 contracted the disease but there was no mortality albeit pneumonia coexisted. In another institution all of the personnel was attacked but only one died. The patients whom they cared for had a high mortality—about 15 per cent of those attacked. Hence precautionary measures sometimes protect outright while at other times they secure a mild course of the disease. The attendant has a much better chance to protect himself than the average man, despite his constant exposure. We may therefore be hopeful of protecting an intelligent and conscientious community in the same manner. As we understand the mechanism of the disease it is as follows: there is an intense congestion of the respiratory tree with the result that the protective power of the epithelium breaks down and allows the germs or their poisons to surcharge the blood. From the fact of sterile blood we have to accuse the latter. Among the phenomena due to intense congestion, one, edema of the uvula, was found to possess great diagnostic significance, being invariably present in the true disease.

Treatment of Varicose Ulcers.—Schlassberg has had remarkably good results from a simple and conservative method of treating these lesions. He publishes fifty cases, from which it appears that only six showed recurrence. His experience extends over seven years. Treatment is carried out with lead plaster, as follows: 24 gms. solution of subacetate of lead were mixed with 136 gms. of lead plaster and then spread on 2,000 sq. cm. of linen or cotton. For a few days after admission a Burrow dressing was applied, the plaster treatment following. The spread plaster was so cut as to project 2 cm. beyond the margin of the ulcer. A firm outside bandage was then applied from ankle to just below the knee. The dressings were renewed daily and when the amount of secretion was large a new piece of plaster was applied. At the other extreme some cases require no change of plaster for three days. The patient is up and about during the entire treatment. A study of the table shows that the patients were all treated in the wards and had all of the advantages accruing from complete control. The duration of hospitalization varied from 21 to 197 days, but the duration of the ulcer before coming under treatment had been as high as ten and twelve years.

December, 1919, xxvii, 74.

What Are Ferments?—Professor Roger has recently delivered alecture on the subject of ferments in his course on comparative pathology. We know what ferments can do, but what are ferments? We have recently obtained the knowledge that they are not protein—that nitrogen is not a necessity in their chemical constitution. Ferment properties are exhibited by lipoids and carbohydrates and whatever a ferment may be it unites in some manner with any of the basic forms of organic existence in such manner as to lose its identity. Ether will extract an enzyme from yolk of egg which contains no nitrogen, is apparently lipoid and exerts a diastasic action. Such a ferment he would term a zymolipoid to distinguish it from the longknown zymoproteid ferments. We have learned that the ferment is in no haste to leave the cell in which it is generated and whil it may be washed into the intestine, for example, and find its way into the blood it exerts considerable activity on the substratum without leaving the epithelium. This is well shown in a loop of intestine which has been washed repeatedly to remove all cellular debris and exclude the possibility of desquamation. If now a solution of saccharose is allowed to pass through the loop inversion of the same can be shown to have occurred. Osmosis in such a case can be excluded. It is not implied that the ferment acts at a distance for it is attracted into the lumen of the gut by the presence of the saccharose; but the ferment cells have not lost their integrity and only a certain amount of enzyme passes out. The element of novelty lies in the force which attracts the ferment to the saccharose. By the same methods it may be shown that the intestinal epithelium contains emulsin. This new knowledge is merely an addendum to the old and does not involve any revolutionary or clinically important departures. It pertains to the cellular ferments as distinguished from the free or excretory ferments.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 26, 1920.

THE PRESIDENT, DR. CHARLES H. CHETWOOD, IN THE CHAIR.

Compulsory Health Insurance.—Dr. CHARLES H. CHETWOOD, upon assuming the duties of his office, made this address. He said it was not necessary on this occasion to deliver a profound address, since one of simpler and briefer language fulfilled all the requirements of the constitution. It was appropriate that he should define his position on the question of compulsory health insurance. In plain language he would say that the letter, spirit, and purposes of compulsory health insurance, in any form in which it had been presented for legislative action up to the present time, merited only unqualified disapproval. The false assumption that such a measure was necessary in order to provide proper medical attendance for the laboring classes was without logical reason to support or justify it. Many of those present had given the subject more study and were better able to handle it than he was, but he wished it understood that there was no lack of sincerity in his attitude. In approaching any matter, opinion must be supported by facts. The argument of the advocates of compulsory health insurance was that this measure was necessary in order to protect the workingmen from becoming objects of charity and that it could be made safe for the medical profession. This question had been discussed from many different standpoints, the opinions expressed being influenced by different mental attitudes. There were those trained in the current political thought, not of the highest character, who had the idea that all evils could be corrected by Legislative action, and another class trained under paternalistic forms of government thought it was a good thing. On the other hand, a referendum of the medical profession showed that the majority of physicians opposed it. However, it was not for the medical profession to decide whether this measure was for the public welfare. It was not the single interest of this or any other group of the medical profession to determine whether compulsory health insurance was good for society. In order to arrive at a correct conclusion the views of the different groups directly affected were of interest. These three groups were the corporations or employers, the employees, the medical profession, and the law-making group. After discussing the viewpoints of these groups and showing that none of them was in favor of the measures thus far presented, Dr. Chetwood stated that after all the law-making group was the one which was best fitted to consider what was best for the public in its widest sense. It was not surprising in view of the great mass of conflicting opinion that had been advanced on the subject that many were bewildered. Nevertheless a careful review of the evidence showed that compulsory health insurance was unacceptable to employers, employees, and the medical profession. It was also unacceptable to the law-makers as shown by the fact that no measure had thus far been passed. Dr. Chetwood then argued somewhat at length to show that the principle of compulsory health insurance was not in conformity with American ideals because it separated the people into classes which was contrary to our principles of democracy. He also quoted from the report of the British Trade Union to show that the act in England had proved a failure in most ways. It was claimed by some that statistics in England showed that poverty had been diminished since compulsory health insurance had gone into effect. On closer study of the situation it seemed that the operation of the compulsory health insurance law happened to be coincident with a period of great national prosperity. It might happen that if a compulsory health insurance measure were enacted in this country at the present time when we were passing into a period of great prosperity, statistics could later be adduced, showing that poverty had diminished under the operation of such a measure, which would be entirely out of conformity with the truth. Health conditions in Germany had not improved under compulsory health insurance and were no better than they were in this country. It had been charged that our dispensary system was demoralizing, but even if one accepted that statement (which he did not) two wrongs would not make a right. The dispensary system had played an important part in the evolution and development of medical workers. In closing, Dr. Chetwood characterized compulsory health insurance as Bolshevistic, socialistic, and thoroughly out of accord with American ideals.

The General Prognosis of Syphilis in the Light of Recent Progress.—Dr. S. POLLITZER presented this paper in which he discussed the subject of syphilis from the point of view of its general prognosis as affected by the additions to our knowledge made within the past two decades. These additions were, first, the discovery of the spirochete; second, the Wassermann test; third, the invention of the new arsenical compounds. To these achievements might be added the use of the dark field microscope and spinal puncture for diagnosis and as therapeutic measures. The discovery of the spirochete had added a factor which had enormously improved the general prognosis of syphilis. There was no factor in the prognosis of syphilis that was comparable in importance with early and energetic treatment. The treatment of syphilis by the vigorous exhibition of arsphenamine in its primary stage, while the disease was primarily a local infection and before the organisms had acted long enough on the tissues even to provoke the development of a positive Wassermann reaction, resulted in the immediate cure of the disease in practically every case. It was in its primary stage that the prognosis of a properly treated syphilis was at its very best. It was the correct practice twenty years ago to await the development of secondary lesions, for the purpose of establishing the diagnosis on a firm basis as well as to convince the patient of the correctness of the diagnosis and thereby secure a greater fidelity to treatment. But waiting for the appearance of secondary lesions meant waiting until there was a wide invasion of the system, waiting until there was a profound septicemia established. In the case of any other local infection no one would delay for a single moment the steps necessary to prevent systemic infection. The affections formerly spoken of as parasyphilis, tabes and paresis, Noguchi's discovery of the spirochetes in the tissues of the central nervous system had definitely placed in the group of syphilitic affections, bringing to an end the fifty-nine years controversy as to their nature. The new studies of the spinal fluid had brought out the fact that the foundation for these late lesions of the central nervous system were laid in the early stage of the disease, probably at the time of the first generalization of the spirochete; more than half the cases of syphilis showed evidence of disturbance in the spinal fluid at this early period. On the other hand it was a common observation that our cases of tabes and paresis gave a history of little or no treatment in the early days of their disease. The time to cure tabes and paresis was the time at which the central nervous system was first invaded and before the anatomical lesions that followed many years later had developed. The second great achievement in recent years was the application of the Bordet-Gengou method of complement fixation to syphilis—the Wassermann test. In all the fluctuations of opinion as to the significance and value of this test one fact had remained clear, and that was that a strongly positive reaction meant syphilis. This test had aided in the proof of the syphilitic nature of the late lesions of the central nervous system, of the sclerotic changes of the cardiac valves and of aortic aneurysm, had abolished Colles' and Profeta's laws, and had awakened the profession and the public to the unsuspected extent of the prevalence of syphilis in every community where a systematic inquest had been made. This knowledge had served as the great stimulus to the administration of proper and energetic treatment and insofar had benefited the prognosis of the disease in the individual. Without discussing the moral side of the question, Dr. Pollitzer ventured the assertion that vigorous inunction with calomel ointment applied within two or three hours to the site of inoculation with fresh syphilitic material would prevent systemic infection, and practically eradicate the disease from the human race within a generation. In the second place

the Wassermann reaction was used as an index of the efficacy of treatment and thus as a prognostic sign. It seemed that a negative Wassermann reaction in a syphilitic meant only that there were no foci of spirochetes in the patient sufficiently active to bring about the formation of an appreciable quantity of Wassermann-bodies in the blood; but it afforded no indication of the eradication of the spirochetes in the tissues. They knew that the late syphilitic with a gumma in the skin, or with obvious symptoms of syphilis of the central nervous system frequently presented a negative Wassermann reaction. We knew furthermore that vigorous treatment in the secondary or later stages commonly resulted in a negative Wassermann reaction which subsequently might become positive. As an index of the complete spirochetal disinfection of the patient a negative Wassermann test at a given moment was relatively useless. On the contrary, however, as an index of failure to eradicate the spirochetes a positive Wassermann reaction in the syphilitic under treatment had the greatest value and demanded the continuance of treatment. Dr. Pollitzer discussed the significance of a positive Wassermann in the old symptomless syphilitic with respect to two classes of cases, namely, (1) the syphilitic who had been well treated for several years, whose spinal fluid was negative, who presented no physical evidence of the disease, but whose blood serum persistently showed a strongly positive Wassermann; and (2) a class of elderly patients in whom as the result of a thorough clinical examination a strongly positive Wassermann reaction was discovered as it were by accident, there being no clinical evidence of syphilis. In the first class systematic treatment should be continued for at least three years before relegating the patient to the class of permanently Wassermann positive, and it might be well to continue occasional short courses of treatment for years. As to the second class, the man who had carried his spirochetes for thirty or forty years without even being aware of them might well be allowed to carry them the rest of his days undisturbed. The symptomless Wassermann positive who was well past his fiftieth year should be left alone. With respect to this class the question arose whether one might not be dealing with a condition analogous to that of the healthy carriers of meningitis, diphtheria, or typhoid bacilli. They must, however, not assume too lightly that a given case, without symptoms and Wassermann positive, belonged to this class until they had really subjected the patient to adequate treatment, and had by examination of the spinal fluid excluded the possibility of a still latent syphilis of the central nervous system. In discussing the third great achievement of recent years, the employment of the organic arsenical compounds to which the name arsphenamine had been given, Dr. Pollitzer referred to the extravagant hopes that were entertained ten years ago that a single injection of salvarsan would permanently sterilize the patient infected with spirochetes. In their disappointment that this assumption was not borne out the pendulum had swung too far in the other direction and they had lost sight of the fact that a complete spirochetal sterilization was indeed a frequent achievement. The proof of cure in these cases rested on the permanence of a negative Wassermann reaction, on the freedom from symptoms, already nearly up to ten years, and finally on the frequent occurrence of reinfection with syphilis in these cases. As proof of cure the provocative arsphenamine injection was a futile and often misleading procedure. The only positive proof of cure was a fresh infection. As long as the patient was syphilitic he could not acquire syphilis. Conversely the occurrence of a fresh infection was a proof that he had been free from syphilis. Since the introduction of the new remedies reinfection with syphilis had become a relatively frequent event. In summarizing, Dr. Pollitzer stated that the recent additions to our knowledge had made it possible to attack the disease by prohylaxis at the moment of infection; to recognize the necessity for further treatment in the absence of symptoms; to detect the disease in the central nervous system before clinical symptoms were manifest, and finally, arsphenamine was a remedy incomparably superior to mercury in speed of action as in efficiency. It was inconceivable that the next generation would not reap the benefit of the improved prognosis of syphilis.

Dr. Boleslaw Lapowski said Dr. Pollitzer had given but little attention to the most important point of the subject, namely, the influence of the early diagnosis and early treatment upon the prognosis of syphilis, in other words the important factor of abortive treatment. Some syphilographers were of the opinion, and Dr. Pollitzer among them, that by an early diagnosis and early proper treatment the syphilitic virus could be destroyed and the patient considered cured and permitted to marry and procreate children, provided he was free from manifestations and his blood and fluid reactions were permanently negative. What was permanent? How many years after the infection must a patient be watched and his blood reaction remain negative? At present there were cases known in which five or six years after infection no symptoms appeared and the Wassermann reaction remained negative for that period, but suddenly without any sexual exposure the Wassermann reaction became positive. Before we could say that a drug or a method was effective as a remedy for such a disease as syphilis, it was necessary that the individuals who had been treated should be watched for the remainder of their lives. It was well known that the symptoms of syphilis might not appear for a great many years after the primary infection. How then could anyone in our generation be sure of the effect of his method or drug to such an extent as to pronounce a syphilitic man cured and permit him to marry? But it was claimed that many cases of reinfection had been reported, which had been treated very early, before the appearance or even after the appearance of a positive blood reaction. Here again the question came up, how was the reinfection established? It was the speaker's opinion that as long as we had no means of determining positively when a given syphilitic patient was completely freed from his first infection, we could not accept a reinfection. A negative Wassermann, even, when accompanied with all other clinical requirements, did not establish the absence of the first infection. Dr. Pollitzer said the foundation of general paresis was laid in the early stages of syphilis, and dated from the time when spirochetes entered the central nervous system. At present Levaditi (*Annales de l'Institut Pasteur*, Nov. 1919) by his experimental inoculations seemed to give great support to the idea that a "nerve virus" which developed special affinity to the nerve tissue might play a very important rôle in the development of paresis; and that there were two varieties of spirochetes, one that produced general paresis and one that gave rise to general syphilis. When within six years such advances and changes in our conception of syphilis were promulgated, how could anyone advocate a radical departure in the treatment of syphilis, a departure which was laden with great danger both for the patient and community? It was safer to follow at present the experiences of decades which we acquired in the treatment of syphilis and wait for more substantial proof before adopting *in toto* the new method of treatment.

Dr. L. T. Le Wald called attention to the fact that gastrointestinal syphilis and its treatment had not apparently received a great deal of attention. Professor Warthin of Ann Arbor had called attention to the necessity of revising our ideas of the pathology, diagnosis, and treatment of visceral syphilis, and roentgenologists had studied the subject of gastric syphilis and had diagnosed the condition in cases which in the ordinary course of events would have been diagnosed as malignancy, and the microscopical examination had shown that they were not new growths but interstitial or gummatous changes which had proved to be syphilitic manifestations. Where syphilitic lesions of this kind had been distinguished from cancer they had been treated and successfully cured, or at least the immediate symptomatic effects relieved, and the patients had gone on quite free from the symptoms of malignancy. Some forty such cases were reported from the Mayo Clinic, some twenty or thirty cases in Chicago, and about the same number in New York. He thought it was time that more attention was given to the diagnosis of gastric syphilis than had been in the past.

Dr. Pollitzer, in closing, said that perhaps when he called attention to the fact his paper was limited to twenty minutes he might be pardoned for not having

entirely exhausted the subject of syphilis. A few of the statements made by Dr. Lapowski required attention. So far as he was concerned he could not become much excited over the fact that the Wassermann reaction was not specific for the spirochete, since it was specific for syphilis, unless it meant yaws or leprosy. With regard to the value of a negative reaction, Dr. Lapowski had evidently misunderstood him. He agreed that the negative Wassermann reaction was not proof of freedom from syphilis. In regard to reinfection and the statement that he considered the negative reaction as proof of cure and that when a chancrous lesion appeared later he took that as proof of reinfection, it seemed hardly worth while to say that more proof than that was required to establish a case of reinfection. It was demanded that there should not only be a long period of freedom from symptoms and repeated negative Wassermann reactions, but that there should be a history of exposure, followed by a lesion having the characteristics of an initlal lesion with spirochetes, followed by adenopathies and the whole picture of a fresh infection. As to parasyphilis and two kinds of spirochetes, that subject was to-day just where it was ten years ago. He believed there was but one form, because there was no difference in the organisms of parasyphilis and syphilis either morphologically or culturally. The evidence did not warrant the assumption that there was a special strain of spirochetes, though it had not been disproved. The experiments of Levaditi showed two things. First that attempts to inoculate with the spirochetes frequently failed, because experimentally these inoculations were difficult to make; and, second, that it was possible that the secondary manifestations of syphilis, the roseola, might not appear until after six months or even fail entirely. In considering the questions that related to syphilis as in any other questions one had to exercise a reasonable amount of common sense.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 23, 1919.

DR. SOLOMON WIENER IN THE CHAIR.

Two Cases of Instrumental Perforation of the Uterus with Rupture of the Intestine.—Dr. HARRY ARANOW reported this case, which occurred in a woman 25 years of age, whose family history was irrelevant, and menstrual history normal. Her past history showed that she had had measles, scarlet fever, and rheumatism, and for a number of years had suffered from heart disease (mitral stenosis). Her last menstrual period occurred in January, 1919. She presented herself to her family physician during the latter part of March, complaining of palpitation and dyspnea. He called in consultation an internist, who advised interruption of the pregnancy. Accordingly the family physician performed a dilatation and curettage on April 11, 1919. Shortly after recovery from the anesthesia the patient complained of severe abdominal pain. This grew worse, and about 2 p.m. of April 12, the speaker was called in to see the patient in consultation. She looked anxious and very ill. The face, lips, and hands were cyanosed; respiration was rapid and shallow; pulse rapid and small, but firm and regular. The abdomen was distended, tender, and rigid over its entire extent. On careful inquiry the family physician stated that he was not sure he had recovered the entire fetus, but that he had extracted some tissue which looked suspicious. Fortunately the curettings had not been thrown away, and an examination disclosed several tunica epiploica. Without further delay he ordered the patient sent to Lebanon Hospital, and prepared for operation. She was given ¼ grain of morphine, and at 4 P. M. was operated upon through a median suprapubic incision. The lower abdomen and pelvis were filled with a reddish brown serous fluid. The sigmoid was in part torn away from its mesentery and had several ragged holes, one the size of half a dollar. The peritoneal cavity was carefully sponged out, and the fetal head discovered lying loosely in Douglas' pouch. The sigmoid was carefully walled off with sponges, and the uterus examined. A tear was discovered extending from a little above the internal os, along the right margin at the insertion of the posterior layer of the right broad ligament up to the right cornu. As the patient seemed to be in good condition, he sutured the uterine wall with three layers of chromic catgut, and then resected six inches of the sigmoid, and performed an end-to-end anastomosis. The lower border of the great omentum was brought down around the intestinal sutures and tacked in place with a few catgut sutures. A rubber tube was inserted through the cul-de-sac and a small cigarette drain brought out through the lower angle of the wound. The patient was returned to bed in good shape. The head of her bed was elevated and continuous proctoclysis given. To his surprise this patient made an uneventful recovery. Her bowels moved spontaneously on the fourth day, and she was discharged on the fifteenth day after admission. As often happens in medicine, he saw a similar case a few days later. This patient was admitted to the hospital on April 26, 1919. She gave a history of having had heart disease for a number of years, and influenza eight months ago. Menstruation was normal. She had had two children, one six years of age, and one stillborn. In this instance also the family physician, in consulation with an internist, decided to interrupt pregnancy on account of her cardiac condition. Accordingly, on April 14, an abortion had been attempted. The patient took the anesthetic badly and the family physician failed to obtain any fetal tissue, so after several attempts gave it up and put her back to bed. Shortly afterwards she began to complain of severe abdominal pains, most marked on the left side. The pain was so severe that she obtained no relief by morphine administered hypodermically. The patient grew worse and the speaker was called in to see her in consultation on April 16, 1919. She was lying on her right side with her knees drawn up close to her abdomen and complained of severe pain which was greatly increased by any movement. The abdomen was distended and rigid all over, the rigidity being more marked, however, over the left inguinal region. The temperature was 102°, pulse 120, and respirations 30. Vaginal examination showed a soft closed cervix. The uterus was enlarged and tender, but otherwise negative. The right fornix was free, the left fornix contained a fluctuating and tender mass high in the pelvis. On these findings Dr. Aranow said he made a diagnosis of ruptured uterus, and advised immediate operation. Accordingly the patient was admitted to Lebanon Hospital. Upon entering the peritoneum through a median incision there was an escape of serosanguinnous fluid. The visceral parietal peritoneum was congested, but he could find no evidence of perforation either of the uterus or intestines. In searching for the mass which he felt per vaginam he discovered a retroperitoneal hematoma behind the mesosigmoid and rectum. A hysterotomy disclosed several pieces of decidua and placenta but no fetus. A rubber tube was inserted through the cul-de-sac, and the peritoneum and fascia closed. The skin and submucous tissues were drawn over to the left and an incision made through the conjoined tendon down to the peritoneum. The peritoneum was carefully peeled away until it was possible to enter a pocket containing six or eight ounces of foul-smelling material, composed of blood, serum, and intestinal contents. At the bottom of the pocket a perforation of the intestine about two cm. in diameter was found, with a slight nipple-like projection of the intestinal mucous membrane. As the cavity was undoubtedly infected no attempt was made to close the hole in the intestine but several rubber drains were inserted and the abdominal wound closed. There was a profuse purulent discharge from this pocket, necessitating rubber tube drain and irrigation. During one of these irrigations the whole fetal torso was washed out of the wound. Following this the patient made a complete recovery and was discharged from the hospital twenty-nine days after admission. The first case was interesting because of perforation of the intestine, operation thirty-six hours afterwards, and recovery without peritonitis, with movement of the bowels four days after the operation. The second case was of interest because of the unusual location and mechanism of the perforation of the uterus and of the intestine extraperitoneally.

Dr. Frederick C. Holden cited a case coming under his observation some years ago in which a similar accident occurred. In this instance the intestine was brought out through the uterus and cut off and the patient had a fecal fistula through the uterus which finally healed up. Usually such accidents occurred where there was an anteflexed uterus and it was the dilator that did the damage while the curette brought down the intestine. Dr. Holden said he did not understand why in the first case rectal feeding was used after doing the intestinal resection.

Dr. Robert L. Dickinson said that he had seen a case in which the uterus was perforated by forceps. In attempting to get the contents of the uterus the forceps perforated the fundus and also the bowel. The patient was brought in in a dying condition too late for treatment. It was a little strange that men used a curette in a small relaxed uterus. In the pregnant uterus after two and one-half or three months almost all work could be done with forceps, and if one did not exert too much force there was much less danger than with the curette.

Dr. L. T. Le Wald said that the new method of making a diagnosis by means of the *x*-ray after the introduction of air into the peritoneal cavity might be applicable in these cases. An *x*-ray examination might have determined whether the peritoneum was ruptured in the second case. By this method he had been able to diagnose a duodenal ulcer perforation. He thought that by this method they could have made a diagnosis of perforation in this case very promptly.

Dr. Aranow, in closing, said that Dr. Holden's criticism with reference to the rectal feeding was just. It was used by the house surgeon in this case because the patient was put to bed in very bad condition; it was, however, a dangerous procedure in low resections. In reference to the introduction of air into the abdominal cavity, they did not know whether there was a perforation of the intestine, and furthermore the method had not been worked out at that time. He would like to have had the question discussed whether in the presence of a perforation conservatism was not wise, and whether one should do a resection and a hysterectomy or do a resection alone and try to get along by leaving the uterus, or finally whether a hysterectomy should be done and a fistula left and operated on later.

Monstra Duplica (Terata Cata-anadidyma.)—Dr. George L. Brodhead reported this case. He said that the mother of the double monster was a young negress, a primipara, aged 30 years, who went into labor at term. Her physician informed him that after a normal first stage the head of the first child was born spontaneously. As there was no further progress he extracted the arms, trunk, and legs manually. He then discovered that the child was connected with a second still *in utero*, and an ambulance was summoned the patient being carried to the Harlem Hospital where she was placed at once on the delivery table. While the nurses were busy preparing her for operation, and unfortunately while no one was carefully observing her, she gave birth spontaneously to the second child. In all probability birth took place by spontaneous evolution, but of this they were not positive. The children were born dead, but had been alive up to the time of labor. The weight of the monster was 11¼ pounds, the sex was female, and, as seen in the specimen and photographs, the children faced each other and were united by a hood attachment which extended from the ensiform to a point which was just below a common umbilicus which showed a large ventral hernia. There was one umbilical cord and a placenta. The children were very similar in appearance and apparently identical in measurements and weight. The patient completed her labor normally, had no perineal laceration, and the puerperum was uneventful.

Pregnancy in the Rudimentary Horn of a Bicornate Uterus.—Dr. George L. Brodhead reported this case. He stated that Dr. Lee, in his recent text book of obstetrics, stated that this condition closely resembled ectopic gestation. The first case was reported by Mauriceau and Vassal in 1669, and since then more than 100 cases have been reported. The rudimentary horn might be closed at either end, making pregnancy impossible, but accumulation of menses probable. Should the fertilized ovum be inserted in the small horn, there was no hope of reaching the uterus, because the connecting bridge of tissue was usually imperforate. The ovum might grow to term, but the gestation sac usually ruptured in early pregnancy, followed by severe internal hemorrhage. The patient, aged 30, was a V-gravida, having had four previous normal confinements, the last of one-half hour duration. In this instance pregnancy proceeded to about the eighth month, the only symptom being occasional pain in the left hypogastrium. At 7 A. M., on the day of admission to the Harlem Hospital, there was slight pain in the left half of the abdomen, and the patient complained of slight occasional pains up to the time of admission at 2.30 P. M. No life had been felt for two days, and the midwife had diagnosed death of the fetus, for which cause the patient was sent to the hospital. At about 3 P. M. she was apparently in good condition, but at 3.15 she was found in shock and pulseless. Dr. Langrock, who saw the patient first, gave 1,200 c.c. normal saline solution intravenously, but the woman's condition was desperate when the speaker arrived shortly afterward, and in a few minutes she died. Abdominal palpation revealed a fetus apparently free in the cavity, and the cervix was safe and closed. A diagnosis of ruptured abdominal pregnancy was made and also a post-mortem abdominal section, a large amount of blood being found in the cavity with the child. The child weighed 4 10/16 lbs. and was dead, though showing no maceration. As it was impossible to determine the exact variety of pregnancy without thorough microscopical examination of a number of sections, this had been done for him by Dr. Strong and Dr. Schwartz. The report submitted by them stated that the diagnosis was uterus bicornis with rudimentary left horn and pregnancy of approximately eighth months duration in this horn (decidua in the uterus, corpus luteum of pregnancy in the left ovary). Among the interesting features of the case were the following: (1) The patient had been four times pregnant in the right horn of the uterus, before becoming pregnant in the rudimentary left horn. (2) The left horn contained the corpus luteum of pregnancy. There was a well marked fimbriated extremity of the left tube but no tube could be discerned. (3) The uterus seemed to be no larger than the usual size before pregnancy and seemed to have developed from the right Müllerian duct.

Dr. Dickinson asked Dr. Brodhead to draw a diagram showing which was the fetal sac.

Dr. Brodhead drew a diagram showing the rudimentary left horn of the bicornate uterus just above the cervix and just above this what seemed to be the round ligament.

Dr. Holden asked Dr. Brodhead what his diagnosis was.

Dr. Brodhead replied that they thought they were dealing with an abdominal pregnancy of some type, but they did not suspect the true condition until section was made.

Dr. Robert T. Morris said that, in the first case, from the biological standpoint it would be interesting to know whether these twins were from one ovum or from two ova.

Dr. Arnold Sturmdorf asked Dr. Morris how he would determine the origin of those twins from one ovum or from two ova.

Dr. Morris replied that if the twins were absolutely similar he would consider that they came from the identical ovum.

Dr. Sturmdorf said that he had had occasion to study Graafian follicle development and the embryology of the female genitalia in their relation to the pathology of endotrachelitis. According to recent conceptions based upon the original investigations of Kolliker, Dr. Brodhead's case was *not* one of bicornate uterus, but a unicornate uterus with pregnancy in an anomalous tube. The relation of the existing fimbriated extremity and ovary substantiated such an interpretation. It must be recalled that developing from the fusion of the two Müllerian ducts, every uterus was bicornate at a certain stage of its development, and that a portion of each horn subsequently remained as tube. The presence of musculature, similar to uterine muscle, in the tubal wall was natural and a usual finding under the circumstances, but the epithelial lin-

ing of the tubal lumen was not that of the corporal endometrium.

Dr. BRODHEAD, in closing, said he could say nothing in reference to the arguments Dr. Sturmdorf had brought forward to show that the section was of a tubal and not a rudimentary horn of a bicornate uterus, because he had given the specimen to Drs. Strong and Schwartz of the Woman's Hospital who stated positively that it was a rudimentary horn and he had taken their word for it.

Rapidly Growing Multilocular Ovarian Cyst Associated with Complete Amenorrhea.—Dr. GEORGE W. KOSMAK presented a report of a case in which amenorrhea and certain subjective evidences of pregnancy led to a diagnosis of the latter condition in association with an abdominal tumor. The case was reported, he said, for the purpose of calling attention to this peculiar combination of symptoms which might readily lead to an erroneous diagnosis. The patient was 31 years of age, married May 18, 1919. Her menstruation had always been fairly regular and she was menstruating at the time of her marriage. A slight spotting occurred in June and in October she bled a few days during a cold contracted at this time. There was no nausea or vomiting until October, when she also began to cough. The vomiting became gradually worse and she lost considerably in weight. She felt worse at night and was very constipated. A gradually increasing abdominal tumor was noted and the patient and her family believed her to be pregnant. She was first seen December 2, 1919, in consultation. Examination showed a rather sick looking young woman, not well nourished, conjunctivæ pale, eyes sunken, skin dry, heart and lungs negative. The abdomen was uniformly enlarged to the ensiform, rigid, somewhat tender, with the skin smooth and tense, umbilicus flat, no fetal sounds or ballottement possible. There was no secretion present in the breasts. A bimanual examination failed to outline the uterus, but the cervix was soft, admitted finger tip and simulated that of pregnancy. A preoperative diagnosis was made of pregnancy associated with a neoplasm, and in view of the patient's increasing pain, obstinate vomiting, and general decline, operation was decided upon. A median incision was made from an inch above the symphysis to above the umbilicus. The abdominal wall was moderately edematous. On attempting to enter the peritoneal cavity firm adhesions were encountered between the parietal peritoneum, and a large tumor mass which on exploration was found to occupy the greater part of the cavity, extending from the brim of the pelvis practically to the liver. The entire anterior portion of the growth was quite firmly adherent to the abdominal wall. A diagnosis of a large multilocular cyst was made and in order to avoid extending the abdominal incision the portion under the wound was opened and several quarts of a dark-colored fluid containing numerous gelatinous masses allowed to escape. The size of the tumor being thus reduced it could be dragged down through the original incision and was found to be attached by a broad base to the left broad ligament. The pedicle was clamped and the growth removed, the left tube being included in the excised mass. The uterus was displaced to the right side and the right tube and ovary found to be normal. The intestines had been packed in back of the mass and were covered by the omentum, which was not adherent to the tumor. The abdominal wall was closed in three layers, using plain catgut, including a subcuticular suture. The patient took the anesthetic well and made an uneventful recovery. The vomiting stopped in a few days and the wound healed by primary union. The pathological diagnosis was cystadenoma of the ovary. Attention may be called to the almost absolute menorrhea starting at the time of the patient's marriage, together with a uniformly growing abdominal tumor and subjective evidences of pregnancy. The rate of growth exceeded that of a normal pregnancy of the elapsed periods and combined with evidences of intraabdominal disturbance, dictated immediate operation.

Dr. L. T. LEWALD said that perhaps he should offer an apology for introducing the subject of pneumoperitoneum again. This was another case in which introduction of air into the peritoneal cavity might have thrown light. It would have been interesting to know in this instance whether the *x*-ray after pneumoperitoneum would have shown adhesions to the abdominal wall. In this case it would have been very difficult to introduce the needle, and it was a question whether a diagnosis could have been made by the introduction of air into the peritoneal cavity or whether it was one of those cases in which this procedure would have failed or would have been dangerous.

Dr. KOSMAK, in closing the discussion, said he had not seen amenorrhea associated with bilateral dermoid cyst. The diagnosis in this case had been particularly difficult and he did not see how they could have introduced air into the abdominal cavity. He was glad this was not attempted because the tumor might have been perforated. Cases of this kind were often admitted to the Lying-in Hospital in which associated with the pregnancy there was an abdominal tumor, and he did not know how they were to make the distinction in cases of this kind. The abdomen was tense and difficult to palpate and bimanual examination was equally unsatisfactory. The only points by which one could be guided were the amenorrhea and the size of the uterus. The patient stated that the amenorrhea had lasted for over five months but the size of the uterus did not correspond to a five months pregnancy. Only a week later they had had another case with a very similar history in which it was also very difficult to make a diagnosis by palpation. There was, however, secretion present in the breast but the size of the uterus did not correspond to the period of amenorrhea. Severe abdominal pain and other signs indicated operation, and when she was opened a five months' pregnancy was found, and three fibroid tumors, a rather small one in the wall of the uterus, a larger one beginning to break down, and a third one packed into the brim of the pelvis. In order to get at the one in the posterior wall the uterus had to be lifted out of the abdominal cavity. This woman continued with her pregnancy. These two cases presented the same train of symptoms, the only difference was that in the one case there was a distinct secretion in the breasts and in the other there was not.

X-ray Illustration of Normal and Abdominal Position of the Uterus.—Dr. DOUGAL BISSELL gave this demonstration. He stated that the requisites for getting good *x*-ray pictures showing the position of the uterus were that the woman should be thin, that she should have a relaxed perineum, a canal somewhat accessible, and a somewhat patent internal os. The first plates showed what he considered to be the normal position of the uterus with the patient in the standing posture. In all the textbooks the standard position of the uterus was taken as the position this organ assumed when the bladder was half full. When the bladder was half filled or contained a greater quantity of fluid the angle that the uterus made with the horizontal plane differed greatly from that made when the bladder was empty. It did not seem to him that this way of determining the position of the uterus was sufficiently accurate and definite to determine the standard or normal position of the uterus. When the bladder was empty it was found that the uterus lay in practically a horizontal position, its angle with the horizontal plane being between 14 and 20 degrees. Plates were shown of a typical case of enteroptosis. This patient had all her viscera displaced; both kidneys were very low; the stomach and intestines were low and the uterus was retroverted. He had corrected the position by splitting and overlapping the round ligaments, and had succeeded in leaving the uterus in good position. One could take a series of pictures showing the position of the uterus with the bladder filled to different degrees. Instead of using an injection of thorium to get the pictures he used an iron stem because the thorium was not retained nor was it of sufficient density to show through the bony structure of the pelvis. Another plate showed the uterus at an angle of 16 degrees with the horizontal plane. The patient from whom this picture was taken had been operated upon for tuberculous kidney. His method of doing this operation was to open the abdomen and dissect out the ureter for its entire length down to and under the uterine artery. In doing this he found an adherent ovary and tube and the uterus was retroflexed and did not assume the anterior position. The

angle between the axis of the vagina and that of the uterus was 40 degrees. The picture showed the same woman with her uterus in the normal position. Another plate showed a woman wearing an Emmett pessary covered with tin foil. In view of the finding that the normal position of the uterus was in an almost horizontal plane it would be desirable to change the nomenclature and instead of speaking of the anterior and posterior surfaces of the uterus to call the anterior the inferior surface and the posterior the superior surface of the uterus. Dr. Bissell exhibited a series of pictures showing various degrees of displacement. One of these showed that it was possible strictly speaking to have a procidentia uteri without having a cystocele or rectocele. The pictures showed the cervix on a level with the coccyx and by pressing the tip of the finger upon the cervix it could be pressed against the coccyx.

Dr. George Gray Ward asked if he was correct in understanding that the pictures were taken after the round and broad ligaments had been shortened.

Dr. Bissell replied that he was. The pictures were taken after the round ligaments were shortened.

Dr. Ward asked if it was not possible that the uterus was overcorrected and was not in an absolutely normal position.

Dr. Bissell said that would have to be proved by having the bladder filled with fluid and then if the uterus was mobile it would go back to the sacrum. He had not done that in this case but was satisfied that it could be done.

Graphic Measurements of Operative Results.—Dr. Robert L. Dickinson made this presentation, in which he urged the introduction of Bronton's graphic methods into medical textbooks. He said there was no industry that did not have in the office of the manager a collection of swinging leaves from which the manager could show at a glance what each man was producing, and whether costs were increasing or decreasing. These methods were so common in other walks of life and so useful that they ought to be introduced into medicine. He had been working along these lines and had devised a scheme for hospital use, which showed at a glance what every man on the hospital staff was doing, the operations he had performed, the area of frequency, and many other details. A great deal of data could be presented in a graphic way that could be grasped by the mind at a glance and meant a great deal more than statistics.

Dr. Dickinson then gave a lantern slide demonstration of his method of keeping graphic case histories. One of the most interesting figures showed that if a lead tape were introduced into the uterus and then an *x*-ray examination made the exact position of the uterus could be seen in the picture. The two points from which measurements were then taken were the symphysis and the coccyx, and in its normal position the cervix was on a line drawn between these two points, two and one-half inches from the coccyx. The finger, however, was a much simpler measure, taking the subpubic arch as a starting point. One inch was allowed for each phalanx, and one inch allowed from the knuckle to the base of the thumb. With the diagram of the pelvic floor showing the distance from the pubic arch to the coccyx as three inches, and the finger as a measure, one could work out very satisfactory results. Of 150 cases of which he had kept graphic records, he had selected 50 to demonstrate the kind of diagrams that he made before operation, at operation, and perhaps subsequently. By recording such diagrams with the case histories one could tell in a moment more than he could by reading the written record. There were many instances in which the possession of such diagrams would be of great medicolegal value.

New Ideas on the Spirochete.—Mme. Fuchs-Wolfring does not understand why in inoculation of pure cultures of the treponema the results are only exceptionally positive. As far back as 1911 Spengler announced the discovery of atypical spirochetes in the blood, which are granular and ovoid. The defects of our knowledge appear to be due to the fact that only typical organisms have hitherto been accepted as the cause of syphilis. Spengler finds the atypical germ in the blood in florid syphilis, and makes use of the find in diagnosis as a check on the Wassermann test.—*La Presse Médicale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, State of Colorado.

October, 1919.

ANATOMY.

1. Define—Anterior fontanelle, dura mater, fissure of Rolando, fundus oculi, foramen of Winslow, and duct of Wirsung.
2. Describe the upper extremity of the ulna.
3. Give attachments, action, and nerve supply of the following muscles, Subscapularis, latissimus dorsi, pronator radii teres, psoas magnus, and sartorius.
4. How does the facial nerve emerge from the cranium? What muscles does it supply? Describe the facial appearance in paralysis of the seventh nerve.
5. Describe the axillary artery.
6. Describe the location and formation of the superficial and deep palmar arches.
7. Describe the large intestine as to size and location, subdivisions, blood supply, and mesentery.
8. Describe Poupart's ligament and the saphenous opening.
9. Explain why each male has a potential inguinal hernia; its incidence in male and female as compared to femoral hernia.
10. Discuss the uterus as to its size and structure, its blood supply, and its relation to the peritoneum.

PHYSIOLOGY.

1. Explain the difference in the action of ptyalin on raw and cooked starch.
2. From what portion of the cortex cerebri do the arm, the face, and the leg receive their motor impulse?
3. Mention the enzymes of the pancreatic juice and state the function of each.
4. How is the automatic action of the heart muscle supposed to be maintained?
5. What general conditions influence blood pressure and blood velocity?
6. Discuss the origin and significance of urea.
7. Give the reaction of the following, and state the cause of reaction: Gastric juice, blood, urine, pancreatic juice.
8. State briefly what is meant by the vasomotor nervous system of the body.
9. What are carbohydrates and what part do they play in the general metabolism of the body?
10. Describe the physiology of menstruation.

CHEMISTRY.

1. Give the formulæ and chemical names of the following substances: (*a*) Saltpeter, (*b*) Epsom salt, (*c*) Paris green, (*d*) aqua fortis, (*e*) gypsum, (*f*) Glauber's salt, (*g*) Rochelle salt.
2. Define (*a*) isomerism, (*b*) metamerism, (*c*) polymerism, with examples of each.
3. Define with examples, (*a*) Basic radical and (*b*) acidulous radical, (*c*) hydride, (*d*) hydroxide, (*e*) haloid salt, (*f*) binary compound, (*g*) anhydride.
4. What are the chemical processes underlying fermentation and putrefaction? Give example.
5. Define (*a*) alcohols, (*b*) ethers, (*c*) phenols, (*d*) alkaloids, with examples.
6. Define the terms metabolism, catabolism, and anabolism.
7. Define (*a*) physiological salt solution, (*b*) isotonic, (*c*) hypoisotonic, and (*d*) hyperisotonic solution.
8. What is the source of urea in the body, its normal quantity, and the significance of its (*a*) increase (*b*) decrease.
9. Define (*a*) proteins, (*b*) albumin, (*c*) peptones, (*d*) albuminoids.
10. Name the most important reagents for uranalysis with the uses of each.

ANSWERS.

ANATOMY.

1. *Anterior fontanelle* is a diamond-shaped space found in infants, situated between the parietal and frontal bones.

Dura mater is the outer of the three membranes covering the brain and spinal cord.

Fissure of Rolando is a fissure situated about the middle of the outer surface of each cerebral hemisphere, beginning just behind the middle of the longitudinal fissure and running downward and forward.

Fundus oculi is that part of the interior of the eyeball which is situated around the posterior pole.

Foramen of Winslow is a foramen connecting the general peritoneal cavity with the lesser peritoneal sac.

Duct of Wirsung is the excretory duct of the pancreas.

2. The *upper extremity of the ulna* is large and irregular and presents the olecranon process, the apex of which is received into the olecranon fossa of the humerus; the triceps muscle is inserted in its upper border; the lateral ligaments are inserted at the sides. The coronoid process projects from the anterior surface and is received (during flexion) into the coronoid fossa of the humerus. The great sigmoid cavity is on the upper surface, and the lesser sigmoid cavity on the outer surface.

3. SUBSCAPULARIS. *Origin:* Subscapular fossa. *Insertion:* Small tuberosity at upper end of humerus. *Action:* It flexes the humerus and rotates it inwards. *Nerve supply:* Subscapular.

LATISSIMUS DORSI. *Origin:* Spinous processes of lower six dorsal vertebræ, lumbar aponeurosis, supraspinous ligaments. *Insertion:* Bicipital groove of humerus. *Action:* It draws the arm downward and backward, and rotates it inward. *Nerve supply:* Long subscapular.

PRONATOR RADII TERES. *Origin:* Internal condyle of humerus and ridge just above it; also from inner border of coronoid process of ulna. *Insertion:* Middle of outer surface of radius. *Action:* It flexes the elbow and pronates the forearm. *Nerve supply:* Median.

PSOAS MAGNUS. *Origin:* Transverse processes and bodies of all the lumbar vertebræ and the body of last dorsal vertebra. *Insertion:* Lesser trochanter of femur: *Action:* It flexes the thigh on trunk, or trunk on thigh, and also rotates the femur outward. *Nerve supply:* Branches from lumbar plexus.

SARTORIUS. *Origin:* Anterior superior spine of ilium. *Insertion:* Inner side of tibia by the side of the tubercle. *Action:* It flexes the hip and knee, abducts the thigh and rotates it outward. *Nerve supply:* Anterior crural.

4. The FACIAL NERVE leaves the cranium through the stylomastoid foramen. It *supplies* the muscles of the face, scalp, external ear, buccinator, platysma, stapedius, stylohyoid, and posterior belly of the diagastric.

"When it is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheeks are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums." —(Kirkes' *Physiology.*)

5. The *axillary artery* is the continuation of the subclavian; it begins at the outer border of the first rib and extends as far as the lower border of the tendon of the teres major, where it becomes the brachial artery. It is deeply situated at its origin, but is quite superficial at its termination. It is divided into three parts by the pectoralis minor muscle; the first part being above that muscle, the second part behind it, and the third part below it. Its *branches* are: Superior thoracic, acromio-thoracic, long thoracic, alar thoracic, subscapular, and anterior and posterior circumflex.

6. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches. The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm. The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries. The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch.

7. The large intestine extends from the termination of the ileum to the rectum. It differs from the small intestine in: (1) Its larger size; (2) its more fixed position; (3) the possession of teniæ; (4) in being sacculated; and (5) in possessing appendices epiploicæ.

The colon is divided into ascending, transverse, descending, iliac, and pelvic. The *ascending colon* extends from the cecum to the under surface of the liver to the right of the gall-bladder, where it turns to the left, forming the *hepatic flexure.* It lies in the right iliac and right hypochondriac regions. The peritoneum covers the anterior and lateral surfaces. Length, 8 inches. The *transverse colon* passes from right to left, from the gall-bladder to the spleen. It forms an arch, convex anteriorly, and below: the *transverse arch of the colon.* It is entirely surrounded by peritoneum, which is attached posteriorly to the spine, forming the mesocolon. Length, 20 inches. The *descending colon* passes from the end of the transverse colon by a bend, *the splenic flexure.* Between the splenic flexure and the diaphragm, opposite the tenth left rib, is a fold of the peritoneum, the *costocolic ligament,* which slings up the spleen. The gut then passes downward to the iliac crest, ending in the iliac colon. The peritoneum invests its anterior and lateral surfaces. Length, 4 to 6 inches. The *iliac* colon is continuous with the descending colon at the left iliac crest, and ends at the inner border of the left psoas. Peritoneum invests its anterior and lateral surfaces: it has no mesentery. Length, 5 to 6 inches. The *pelvic colon* extends from the inner border of the psoas to the level of the third sacral vertebra. Length, 16 or 17 inches; very variable. It has an extensive mesentery.—(From *Aids to Anatomy.*)

BLOOD SUPPLY TO THE LARGE INTESTINE. *Cecum and appendix:* Ileocolic and appendicular arteries. *Colon:* Right colic and middle colic (of superior mesenteric), left colic and sigmoid branches (of inferior mesenteric). *Rectum:* Superior hemorrhoidal (of inferior mesenteric), middle hemorrhoidal (from internal iliac), and inferior hemorrhoidal (from internal pudic artery).

8. *Poupart's ligament* is the lower border of the aponeurosis of the external oblique, and extends from the anterior superior spine of the ilium to the spine of the pubis.

The anatomical structures which lie beneath Poupart's ligament are (from without inward): External cutaneous nerve, Iliacus, anterior crural nerve, Psoas, femoral artery, femoral vein, femoral ring.

The saphenous opening is an aperture in the fascia lata, situated at the upper and inner part of the thigh a little below Poupart's ligament. It transmits the internal saphenous vein.

9. *Inguinal hernia* is more common in the male because the inguinal canal is larger, owing to its having allowed the passage through it of the testis. The ratio of inguinal to femoral hernia is given as 96: 2 in the male, and 50: 33 in the female.

10. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity, and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine.

The *uterus* is composed of an external or serous coat, a middle or muscular coat, and an internal or mucous coat. The serous coat is derived from the peritoneum and covers the fundus and posterior surface; the anterior surface is covered as far as the junction of the cervix with the body. The muscular coat forms the bulk of the uterus, and is arranged in three layers, an outer, middle, and inner. The mucous membrane is adherent to the muscular coat, it lines the uterus

throughout, and is continuous with the lining of the vagina and also with the Fallopian tubes and peritoneum. The *arteries* supplying the uterus are the uterine and ovarian.

PHYSIOLOGY.

1. The action of ptyalin on cooked starch begins promptly; if raw starch is used the action of the ptyalin is much delayed. This is said to be due to the fact that raw starch grains are surrounded by cellulose, and that this cellulose resists the action of the ptyalin; cooking the starch breaks up this cellulose envelope and allows the ready access of the ptyalin to the starch granule. Further, when starch is boiled it takes up water, and then it is acted upon more quickly by the ptyalin.

2. The *motor areas* are located and arranged on the cerebral cortex immediately in front of the fissure of Rolando. At the upper part of the convolutions in front of this fissure are areas connected with the movements of the lower extremities; then from above downward are located the centers for movements of the shoulders, arms, wrists, fingers, face, lips, tongue, and larynx and pharynx.

3. ENZYMES OF THE PANCREATIC JUICE. *Amylopsin*, an amylolytic enzyme, hydrolyzes undigested starch or dextrin to maltose, and later on this is converted into glucose, fructose, and galactose. *Trypsin*, a proteolytic enzyme, hydrolyzes protein to amino-acids, at the same time yielding proteoses, peptones, and polypeptides. *Steapsin*, or pancreatic lipase, converts the fats into glycerol and fatty acids.

4. *Automaticity of the Heart.*—"The question of the cause or causes of the automatic rhythmical contractions must be sought for whether the phenomenon turns out to be a property of the muscular tissue or of the nervous tissue of the heart. When we say that a given tissue is automatic we mean that the stimuli which excite it to activity arise within the tissue itself, and are not brought to it through extrinsic nerves. In the heart, therefore, we assume that a stimulus is continually being produced, and we speak of it as the *inner stimulus*. Experiment and speculation have been directed toward unraveling the nature of this inner stimulus. Most of the physiologists who have expressed an opinion upon the subject have sought an explanation in the composition of the blood or lymph bathing the heart tissue, or in the products of metabolism of the tissue itself. Regarding this latter view there is nothing of the nature of direct experimental evidence in its favor. No product of the metabolism of the heart tissue capable of exerting this stimulating effect has been isolated. In regard to the former view, that the inner stimulus is connected with a definite composition of the blood or lymph, there has been considerable experimental work which is of fundamental significance. While the older physiologists paid attention mainly to the organic substances in the blood, it has been shown in recent years that the inorganic salts are the elements whose influence upon the heart beat is most striking. These salts are in solution in the liquid of the tissue, and are therefore probably more or less completely dissociated. Attention has been directed mainly to the influence of the cations, of which three are especially important, namely, the sodium, the calcium, and the potassium."—(Howell's *Physiology*.)

5. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls. Blood pressure:

MAY BE RAISED	MAY BE LOWERED
1. By the heart beating more quickly.	1. By the heart beating more slowly.
2. By the heart beating more powerfully.	2. By the heart beating more feebly.
3. By contraction of the arterioles.	3. By dilatation of the arterioles.
4. By increase in total quantity of blood.	4. By deficient supply of blood to the left ventricle.

Blood velocity is similarly influenced.

6. The greater part of the urea produced in the body is formed in the liver. The liver cells form the urea from two sources: (1) The larger amount, produced by the liver cells, is derived from the amino-acids which have been absorbed from the small intestine, and which are not required by the tissues; this constitutes the *exogenous* urea. (2) The smaller amount, produced by the liver cells, is derived from the ammonium carbonate, which is the outcome of nitrogenous catabolism, and which is derived from the tissues; some is also produced by the action of the uricolytic enzyme upon uric acid; this constitutes the *endogenous* urea.

The amount of *urea* eliminated in the urine depends largely upon the amount of nitrogen contained in the food, and also upon the extent of protein metabolism going on in the body. It is increased in fevers, in diabetes, pneumonia (during resolution); it is decreased in diseases of the liver.

7. *Gastric juice* is acid in reaction, due to hydrochloric acid; *blood* is alkaline, due to disodic phosphate and sodium carbonate; *urine* is acid, due to monosodic phosphate and organic acids; *pancreatic juice* is alkaline, due to sodium carbonate and sodium phosphate.

8. The vasomotor nervous system consists of (1) a vasomotor center in the bulb, (2) of some subsidiary centers in the spinal cord, and (3) of vasomotor nerves, which are of two kinds: (*a*) those causing constriction of the vessels, and so-called vasoconstrictor nerves; and (*b*) those causing dilatation of the vessels, and so-called vasodilator nerves. These nerves supply the muscle tissue in the walls of the blood-vessels and regulate their caliber, thus influencing the *quantity* of blood supplied to a part; at the same time they regulate the *quality* of blood supplied to a part; they also regulate the *nutrition* of a part, also *secretion* and *heat production*. They are concerned, too, in the control of the heartbeat. The center is in the medulla, in the floor of the fourth ventricle, near the calamus scriptorius.

9. *Carbohydrates* were formerly defined as substances of unknown constitution containing carbon, hydrogen and oxygen. The molecule of carbohydrate contained six atoms of carbon (or some multiple of this number), and the hydrogen and oxygen were present in the proportion required to form water. While this definition is not, to-day, scientifically accurate, it suffices to "label" a definite class of compounds containing the sugars and starches.

Carbohydrate metabolism.—"The carbohydrates pass into the liver by the portal circulation as dextrose, and are partly stored up in the liver cells as glycogen, to be given off as sugar in the periods between digestion, to be used up when a sudden demand is made by the starving or working body. Carbohydrates may also be derived from proteids. The dextrose is used up by the muscle and gland-cells being oxidized, the carbon going off as carbon dioxide. As to amount of carbohydrates, only 500 grams can be consumed without digestive disturbance. The carbohydrates are found in small proportions in fleshfoods, such as glycogen, and in milk in the form of lactose. By far the greater proportions of carbohydrates are obtained from the vegetable kingdom. In vegetable foods they occur as starches and sugars. An animal that is fed upon carbohydrates exclusively dies of starvation on account of want of proteid. The saving of proteid increases proportionately with the quantity of carbohydrates ingested. This is an important fact, since the digestive juices are capable of digesting them in large quantities."—(Ott's *Physiology*.)

10. *Physiology of menstruation.*—"The endometrium, in the four or five days preceding the flow, becomes rapidly thicker and its superficial layers are congested with blood and, in places, small collections of blood may be noticed. Opinions differ very much as to the change undergone by this thickened membrane during the flow. According to some authors, most of the membrane is thrown off and the blood escapes from the denuded surface mixed with pieces of the membrane. According to others, no material destruction of the membrane occurs, the blood that escapes being due to small capillary extravasations or perhaps mainly to a process of diapedesis. It would seem that the amount of destruction of the endometrium must be subject to invididual variations. After the cessation of the flow

the mucous membrane is rapidly repaired by regenerative changes in the tissues; the surface epithelium, if denuded, is replaced by proliferation of the cells lining the uterine glands and the thickened, edematous condition of the membrane rapidly subsides during a period of six or seven days. The mucous membrane of the uterus may be said to exhibit a constantly recurring mentrual cycle which falls into four periods: (1) Period of growth in the few (five) days preceding menstruation, characterized by a rapid increase in the stroma, blood vessels, epithelium, etc., of the membrane. (2) The menstruation or period of degeneration (four days) during which the capillary hemorrhage takes place and the epithelium suffers degenerative changes and is cast off more or less. (3) The period of regeneration (seven days) during which the mucous membrane returns to normal size. (4) The period of rest (twelve days) during which the endometrium remains in a quiescent condition."—(Howell's *Text-book of Physiology.*)

CHEMISTRY.

15. *Saltpeter* is potassium nitrate, KNO_3. *Epsom salt* is magnesium sulphate, $MgSO_4$. *Paris green* is cupric-aceto-metarsenite, $Cu(C_2H_3O_2)_2 + 3\ Cu(AsO_2.)_2$ *Aqua fortis* is nitric acid, HNO_3. *Gypsum* is calcium *sulphate*, $CaSO_4$. *Glauber's salt* is sodium sulphate, Na_2SO_4. *Rochelle salt* is sodium potassium tartrate, $NaKC_4H_4O_6$.

2. Substances which have the same percentage composition but different properties are said to be *isomeric*, or *isomeres* of each other; example, acetic acid and methyl formate.

When substances have the same percentage composition and also the same molecular weight, they are said to be *metameres;* example, acetic acid and methyl formate are metameres as well as isomeres.

When substances have the same percentage composition but the molecular weight of one is a multiple of the molecular weight of the other, they are said to be *polymeres;* example, acetic acid and glucose.

3. A *basic radical* is a radical which can displace hydrogen from acids; example, ammonium, NH_4. An *acidulous radical* is a radical which can be combined with hydrogen to form an acid; example, SO_4. A *hydride* is a binary compound one element of which is hydrogen; example, NH_3, nitrogen trihydride. A *hydroxide* is a compound formed by the replacement of half of the hydrogen of water by another element or radical; example, KOH, potassium hydroxide. A *haloid salt* is the salt of a hydracid; example, NaCl, sodium chloride. A *binary compound* is a compound containing only two elements; example, H_2S, hydrogen sulphide. An *anhydride* is a substance capable of combining with water to form an acid; example, SO_3, sulphuric anhydride.

4. The terms *fermentation* and *putrefaction* are applied to certain forms of decomposition, by which molecules of certain organic substances are split up into two or more simpler molecules. A favorable temperature, moisture, and the presence of a substance (such as a ferment or bacteria) are necessary. When carbohydrates are thus decomposed the process is called *fermentation;* when protein matter is thus decomposed, the process is called *putrefaction.*

5. An *alcohol* is the hydroxide of a hydrocarbon radical; examples, CH_3OH, methyl alcohol; C_2H_5OH, ethyl alcohol. An *ether* is the oxide of a hydrocarbon radical; examples, $CH_3C_2H_3O$, methyl ethyl oxide; $(C_2H_5)_2O$, ethyl oxide. A *phenol* is a substance derived from the benzene ring by substituting the hydroxyl group for one of the hydrogen atoms; example, C_6H_5OH, phenol. An *alkaloid* is an organic, basic, nitrogenous substance, capable of combining with acids to form salts in the same way that ammonia does; most of them are alkaline in reaction and bitter in taste. Examples, strychnine, and atropine.

6. *Metabolism* is the name given to the series of chemical changes which take place in the body during life, and by means of which the body is nourished and energy is liberated. *Anabolism* includes such of these changes are are concerned with the building up of the body. *Katabolism* includes such of these changes as are concerned with the wasting of the tissues.

7. *Physiological salt solution* is a solution of sodium chloride in distilled water containing 0.7 per cent. of the salt; it is isotonic with the blood. An *isotonic solution* is one having an osmotic pressure equal to that of serum. A *hypoisotonic solution* is one having an osmotic pressure less than that of serum. A *hyperisotonic solution* is one having an osmotic pressure greater than that of serum.

8. *Source of urea in the body:* The greater part of the urea produced in the body is formed in the liver. The liver cells form the urea from two sources: (1) The larger amount, produced by the liver cells, is derived from the amino-acids which have been absorbed from the small intestine, and which are not required by the tissues; this constitutes the *exogenous* urea. (2) The smaller amount, produced by the liver cells, is derived from the ammonium carbonate, which is the outcome of nitrogenous catabolism, and which is derived from the tissues; some is also produced by the action of the uricolytic enzyme upon uric acid; this constitutes the *endogenous* urea.

About five hundred grains of urea are excreted daily in the urine.

The *urea in the body is diminished* in old age, starvation, and conditions which interfere with the ordinary processes of protein digestion.

The *urea is increased* when much water is ingested, in the early stages of fevers, in diabetes, and in chronic nephritis.

9. *Proteins* are nitrogenous organic substances of complex composition and unknown constitution. They are found in every cell and tissue of the body, and are indispensable to the "life" of these cells and tissues. They are composed of carbon, hydrogen, oxygen and nitrogen; they may also contain sulphur, phosphorus, iron, copper, or iodine.

Albumin is a simple protein, soluble in water; it includes egg albumin, vegetable albumin, lactalalbumin, and serum albumin.

Peptones are secondary, derived, proteins obtained from the latter by hydrolytic cleavage (such as action of acids, alkalies, heat, enzymes). They are soluble in water, uncoagulated by heat; they give the biuret test.

Albuminoids are simple proteins with the same general structures as other proteins; they are insoluble in all neutral solvents; they occur as a general rule in the skin and in its appendages, and are often called scleroproteins.

10. *An analysis of urine* includes: Estimation of total quantity passed in twenty-four hours, color, odor, reaction, specific gravity, total solids (by aid of Haeser's coefficient). Then examine for albumin by Heller's test, or by heat and nitric acid (HNO_3); then for glucose by Moore's test, with potassium hydroxide (KHO), or with Fehling's solution, which contains copper sulphate ($CuSO_4$), sodium hydroxide (NaHO), and Rochelle salt ($C_4O_6H_4NaK$); then for blood with potassium hydroxide solution (KHO); then for bile pigments by Gmelin's test, requiring nitric acid (HNO_3); then for indican, using lead acetate ($Pb(C_2H_3O_2)_2$), hydrochloric acid (HCl), ferric chloride (Fe_2Cl_6), and chloroform ($CHCl_3$).

Then examine quantitatively for urea, using solution of sodium hypobromite (NaBrO); for chlorides, with silver nitrate solution ($AgNO_3$); for sulphates, with barium chloride solution ($BaCl_2$). Acetic acid ($C_2H_4O_2$) will be necessary to acidify alkaline urines.

(*To be continued.*)

Cause of Death in Grippe.—Renaud, who has personally treated over 600 cases of influenza during the pandemic, saw as the essential cause of death pneumopathies with multiple foci of hepatization. The mechanism is either asphyxia or cardiac collapse. There is essentially a pneumococcus sepsis of epidemic character so that the entire picture does not differ essentially from the epidemics of malignant pneumonia which occasionally appear in cold weather. The author had 27 cases of severe type and did not lose one, his management being early repose and digitalis as a background, with adrenalin and pneumococcus serum in more desperate cases, the use of hydrotherapy—in short, the usual treatment for pneumonia.—*La Presse Médicale.*

AN EXPERIMENTAL STUDY IN MENTAL THERAPEUTICS.*

BY L. PIERCE CLARK, M.D.

NEW YORK.

RECOGNIZING that no small part of our present mental therapy has been first suggested or employed by lay workers, many neuropsychiatrists have given not only their nurse assistants a training in mental nursing as ordinarily understood, but have striven to make them aware of the psychogenic factors at work in individual cases, and show the attendant the possibilities of cultivating the proper attitude to overcome the defects encountered in the individual patient. Indeed, many of us have found it valuable to discuss the mental symptoms and case-record with the nurses so that they may grasp in its entirety the principles of mental and physical treatment. Of course, one needs to discriminate carefully between the patent and obvious facts in a case and those which are unessential or problematical. In this way a continued post-graduate course is made possible for the trained attendant, thus keeping alive and keen a therapeutic interest which otherwise might lag or become rigid and stereotyped. We must remember that but little growth in professional knowledge could be expected if medical societies did not afford physicians opportunity for abundant verbal and written reports on case material. Every well organized hospital for mental disease should have meetings of its nursing staff as well as physicians. Indeed, certain set discussions of a broad and comprehensive character upon case material might be held wherein nurses and physicians could jointly associate. While there can be no doubt in exceptional cases a little psychiatric knowledge is a dangerous thing for a nurse, on the whole careful and consistent explanation of properly arranged facts and principles but makes them keener and more ambitious to do good work in their particular province. If nurses working empirically in the past have introduced a number of new remedies, they ought in future to bring out many more valuable contributions. Even those irregular practitioners, often with less mental capacity and aptitude than the well trained mental nurse, have improved and modified our therapy to no small degree. All, therefore, should be considered on their merits, independent of the guild spirit in medicine which has so retarded advancement in the past. It still exists despite intensive effort in medical liberalism. A critical, unbiased judgment, however, is as necessary as an openness of mind.

In mental medicine it is quite apparent that the modern trend to deal with the more intimate life of the individual has hastened our steps in considering new therapeutic measures, and above all it has led us to consider mental diseases as shown in disorders of human behavior more on the basis of actual facts than the special name and diagnosis. Thus mental medicine becomes gradually more liberalized; perhpas in some instances too rapidly so. However, we must make progress as we may, consistent with good common sense.

It is not our concern here to consider the ordinary forms of occupational and amusement therapy such as farm, garden, and shop work, sports, athletics, music, and various artistic pursuits. Admirable as these remedies have proved, only too often they have been urged in a stereotyped manner and made quite distasteful and uninviting to the neurotic and psychotic invalid. Our aim on the contrary has been to seek several new and as yet not fully tried out remedies in a unique and novel setting, and I shall report briefly our experience with this manner of therapeutic approach upon a somewhat heterogeneous group of nervous invalids during a trial period covering several months.

The plan of therapy embraced four classes of school work: (1) Montessori and kindergarten classes for pupil patients and pupil teachers in one group; (2) out-of-door crafts work largely embraced in wood carving and cabinet making; (3) the teaching of English expression in reading, story-telling, and dramatic work, and (4) rhythmic dancing. All the work was undertaken during the past summer, out of doors in the groves and forests of a well-known mountain resort. The types from which the individuals were taken included psychoneurotics, retarded depressants, epileptics, organic palsies with slight physical and mental retardations, and speech disorders. To fill the classes in Montessori and kindergarten work a few normal pupils were admitted. The work was carried out under the supervision of experts in these four special fields who also possessed insight into the nature of the mental defects treated and what was essentially needed for each particular patient.

I. Montessori and Kindergarten Work for Neurotics and Psychotics.—We need not spend time here to digest the work of the Froebel system

*Delivered before the New York Psychiatrical Society, November 5, 1919. Lantern slide demonstration.

of kindergartening nor the more modern, distinct but not unrelated system known as the Montessori Method. No doubt the latter is much superior to the former in training widely aberrant types of abnormal children, especially those of the rest-

Fig. 1.—A serenade. The relaxation exhibited is very noteworthy.

less, antisocial and individualistic type—that kind of child who finds it difficult to take on a systematic régime of educational training such as the kindergarten embraces. A method to be widely adaptable must also be widely modifiable. Indeed, Madame Montessori has again and again reiterated this fact, maintaining that the enduring principle in her method is the *spirit* of the *work itself*, and that those who employ it must possess this spirit and be as flexible as the method

Fig. 2.—Rhythm class, showing the children dancing with the older people.

itself. This, of course, robs the method of that definite procedure so much innately sought for by many educators, and it unfortunately allows for no specific standardization. In consequence there has sprung up many sects and schools of the Montessori Method, each claiming a superiority which in many instances has caused no end of controversy among their several exponents. One thing is certain, however, that the Montessori Method has not only brought out a much more thorough

Fig. 3.—"The Greek Urn," the patients lending themselves to the movements, which are very slow and stately.

re-examination of primary teaching principles, but has developed the general resourcefulness of teaching in those who have practised it. It has also increased the power of pedagogic observation. Many teachers have gained new insight into the possibilities of child-development through their work in the Montessori Method. For practical ends, as neuropsychiatrists our main concern is to find a wider and more flexible principle of educating psychopathic and abnormal children; and that, too, by the aid of those teachers who show a ready spirit of co-operation in our difficult task.

It occurred to me that not only was the Montessori Method of value for psychopathic children, but that under carefully trained teachers as supervisors many patients might be profitably employed as associate teachers as well. To this end we established the summer kindergarten and Montessori school out of doors where psychopathic chil-

Fig. 4.—"The Arrow Dance." The play of the muscles here is particularly good. Note the man, an epileptic, whose costume is incongruous to the setting, and contrast with Fig. 5.

dren could be trained, and wherein my adult patients at the same time could be trained as teachers in the method.

The school work for the day opened with improvised rhythmic dancing and ended with story-

telling and dramatic pantomime. The behavior and reactions of psychopathic children to this form of work are sufficiently familiar to all. Suffice it to say that the gradual induction of the psychopathic pupils with normal children, con-

trary to what is usually held, worked out well. Perhaps success was as much due to the ample supply of teachers as to the free system of teaching which the school afforded. We found that the flexible Montessori Method was of greatest use in beginners to teach consistent concentration and application, but it failed to be sufficiently disciplinary in mental training. So soon as the main principles of mental training had been given, more and more of the regular Froebel kindergarten work was introduced. Nearly all the adult patient-teachers had been educated under old forms of teaching, and it was often impossible for a time for them to follow newer and deductive methods. Their critical prejudices suffered no abatement, though they were mentally ill. They did better on the advanced kindergarten work. It was obvious from our experience that the use of patient-teachers in the Montessori and kindergarten work had to be supervised very closely lest

FIG. 6.—"Canopy Dance" to Chopin's Waltz in G Major. The group took epecial delight in this dance, the music and the motions being particularly enjoyable.

the symptoms of the patient-teachers and their mental attitude interfere with the proper running of such classes. The number of supervising teachers had to be increased owing to their having to look in two pedagogic directions.

Some practical lessons were learned in regard to the native normal pupils. The extreme meagerness of the intellectual opportunities of the inland townsfolk was very obvious. Few had had any chance to develop a constructive imagination in

FIG. 7.—Original pose.

games, sports, or books. This was in such sharp contrast to the city children as to make the situation truly deplorable. Why should not the public schools or playground associations extend their facilities to the rural communities? Why should not the rural-bred child have a community center embracing playground activities, craftswork, folk dancing, and dramatic art to enrich his meager life? For our own purpose as well as to help out the obvious lack in our little native pupils, the rhythms, story-telling, and dramatics were made a part of the school routine. The eagerness with which the country children embraced these additions to the routine work was truly remarkable. Not a little permanent good was added to the work in the social service which we did in having the parents visit the school and in our visiting the children's homes. The tactful suggestions which

FIG. 8.—"Water Dance." Three types of cases. The composition of this picture is particularly graceful.

we were able to offer in making the home life more attractive and worth while helped a great deal.

II. Crafts School.—The work of the Crafts School was largely devoted to the teaching of wood-carving and cabinet work. Aside from the

well-known advantages of the arts and crafts in treating nervous invalids, especially in using it as a means of inducting such patients into any number of lines of healthful occupational interest, we used it for the latent but potent means

Fig. 9.—Group, original pose.

of teaching perception and manual dexterity, and above all, the social adaptations which only too often have been given in a direct and less acceptable manner as bald preaching—the old adage,

To teach as though we taught him not.
As though the thing we taught had been forgot.

Its value was largely owing to the fact that no abstract study was required, the expense and ease of its maintenance being in its favor. Almost all the patients selected for this work had never had any experience in the use of tools and had little or no interests of any sort.

A rather important point was that the head worker in wood-carving was well trained in mental nursing. All demonstrations and talks in carving were given after the actual work had been accomplished; then it was possible to show how inaptitude in the use of the hands and mind had been largely responsible for the poor result. Gradually, as in all occupational work, the patients liked the work for its own sake, instead of looking upon it as merely routine and a means for distracting their attention from morbid symptoms. No doubt carving is excellent for teaching group and teamwork in individuals who are innately antisocial or socially uncongenial. Craftswork is one of the best means to reawaken interest, and under its stimulus many another more subtle change in mental attitude can be brought about. Not only was the carved article useful, but it was made for some definite end, and the work-bench gave an ideal opportunity for exchange of ideas and group talk on ethical and social adaptations. The work was also a topic for conversation in rest periods. Hand in hand with mental improvement there was an increased interest for the work, and the character of the finished object was always a sign of the pupil's improved power to express himself objectively. Just as the conflicting thoughts and obsessive ideas faded away, so did the work show a harmony in the worked design, giving thereby a prognostic guide to the patient's betterment. A work table in the forest grove and an adjacent shed gave ample opportunity for daily work.

III. Expression School.—Probably few not immediately concerned in pedagogic work in its broader aspects are fully aware of the tremendous strides which the modern teaching of English has undergone. Not many realize that there are several distinct schools in teaching English expression, not only for overcoming speech disorders but in the art of general use of language. We have all realized that a certain facility in the technique of speech is absolutely essential to correct stammering and lisping, but few of us are aware how far afield teachers in this special work have gone. Speech technicians, of course, still have their use, and the art of proper neuromuscular training for speech disorders is necessary. But we all know how disheartening is the ultimate prognosis for the average confirmed stammerer if he stops with auditory and visual imagery training. Sooner or later he relapses to nearly his former state of speech disability, particularly if he return to his former surroundings and associations. It is not so much that the principles of training were at fault, but that the system was not broad or comprehensive enough. The average stammerer bears the peculiar marks of his defect not only in speech but in every physical and mental activity, so that he literally "stammers all over his body," as has been aptly stated. All his habits of thought, oral and written, have their peculiar expressions. Unfortunately, in curing speech disorders, the technicians fail in a sufficiently broad psychological training to incorporate proper mental habits with the purely technical type of training which they give. However, there is a small but growing school of special English teachers who are striving to separate themselves from the cosmetic group of art-expressionists as well as speech technicians, and hope thereby to enter into a field for training not only those suffering from speech disorders but all individuals who lack good oral expression. It is unfortunate that this latter phase of their work in English expression is still confined to a few private schools or to those who have the time and means to pay for special training. Here and there a few school boards are striving to make this work an integral part of the public school system. When this principle

shall be generally adopted we may hope that a great deal of our native vernacular and general slipshod speech as a people will disappear.

It occurred to me that this comprehensive approach to the art of English expression might be

FIG. 11.—"The Patriarch" in the center telling a story, the other performers make him the center of the dance, and go off according to their own interpretation of the story.

valuable as a co-operative part of all the other schools for our nervous patients. First of all the idea would find sympathetic support from those doing rhythmic dancing, those at kindergarten and Montessori work with its story-telling and dramatic accessories, as well as those engaged in the crafts and nature study work. The hope was justified, and when it is properly arranged for it promises to become a part of good mental therapeutics. The work was largely individual, and was confined to the so-called natural method of hearing and interpretation of the English language combined with such psychologic training to increase quickness of wit, ingenuity, independence of thinking, foresight, and insight. Thus the individual's life separately and collectively was broadened and deepened. That which has done so much for the stammerer was found exceedingly valuable for all nervous invalids who submitted themselves to the English training. At first it seemed odd that the patients with speech disorders should have a training in "footwork" (physical gymnastics), but soon its advantage was recognized as fully as expressing clear mental concepts in hearing or reading; thus the physical and the mental work in the art of English expression progressed hand in hand.

It would take too much space to detail the individual teachings employed. The English training had to be adjusted and suited to the particular type of mental and physical defect of the nervous as well as the speech patients under training. The general result was to clarify mental interpretations and to give with ease and precision fitting expression to the thoughts and emotions through the intelligent and artistic use of the voice, speech and actions, and thus form a fitting part of the other schools of training in mental therapeutics.

IV. Rhythmic Dancing.—Almost everyone knows that rhythmic dancing has been in vogue for a long time as an amusement, and has been extensively used for cultivation of bodily grace. Latterly a few more discriminating teachers have developed the art for overcoming certain types of nervousness. A few have cooperated with neuropsychiatrists and have been guided by them in laying special stress upon certain kinds of music and rhythmic movements which need to be inculcated to overcome specific defects. The introduction of rhythmic dancing would be of greatest benefit at the end of inactive and bed rest treatments in sanatoria in which the change to gymnasium or outdoor sports seems to be too abrupt for many nervous invalids who are incapable or unwilling to take up active exercise. The value of it would, perhaps, be more psychologic even than physiologic, the weak will could be stimulated and one can thus teach social adaptations and cooperation with the group spirit.

It was interesting to note how each pupil-patient had his particular personal objections to entering the rhythm group even after private lessons had been given. These objections, as might be imagined, were similar to those ordinarily given by shy, timid people in every-day life, but here more tact and general insistence was necessary to gain co-operation. It was found that the patients between the ages of nineteen and thirty-five almost without exception entered easily and whole-heartedly into the spirit of the dance. They received pleasure and value in the work from the start. Physical and mental habits in general "set," so to speak, at an earlier period in the psychotic than in so-called normals. The fact that the dancer, like the singer, can give expression to his emotions without the aid of a musical instrument dawned slowly upon each performer. That he might call upon the mechanisms of his body and obtain results that were beautiful as well as useful came as a surprise. After a time each one was encouraged to try out new combination of rhythms of his own. For many reasons this latter practice is perhaps of more value mentally than following rules. To many it became so fascinating that some even tried to work out

FIG. 12.—Montessori group. Teachers in background, and pupils in foreground; two of the latter are mentally defective.

new dancing scores to music not yet rhythmed.

It is unnecessary to say that most neurotics, especially nonhysterics, either have an inherent defect in sense of rhythm or find great difficulty in acquiring the proper mental attitude to take

up the work. At first all our pupil-patients did even cruder work than is ordinarily encountered in so-called normal groups, and their first attempts were even grotesque, for they apparently had never thought of the body in terms of beauty or graceful motion. One patient suffering from a retarded depression, began her work willingly but in a mechanical manner, weeping and protesting her inability to dance. In a few weeks her extremely awkward movements disappeared, the freedom of the dance succeeded and she became most critical of her performance. Quite characteristic of her type of disorder, she demanded of herself an almost impossible perfection for one so little gifted in natural grace. A man of equal age, a confirmed epileptic, mentally and physically rigid and pedantic, would not allow his interest in the dance to be shown, but after a month's work he astonished everyone by the alacrity with which he cast aside his everyday clothing and donned a simple costume and took a real pride in the performance of the graceful tableaux. Contrary to what might have been expected, a stammering, awkward epileptic youth developed into one of the best pupils, passing from a grotesque poseur to one exhibiting joyous abandon in the dance. As may be imagined, his bodily grace as well as his speech was greatly benefited, and the myoclonic jerks (petit mal moteur) which were a part of his epileptic disorder, were also markedly improved.

Fig. 13.—Another Montessori Group.

A girl slightly retarded mentally, who had in early life shown some cerebellar fits as a sequence to a cerebrocerebellar palsy, took up the work with a cumulative advance on her previous motor training. In these handicapped cerebellar individuals the later use of rhythmic dancing will prove a real boon. The graceful combination of sequential movements in a synergic activity will be of great advantage. This particular girl improved greatly in knee flexibility, power of delicate and precise balancing and the coordination of associated limb and arm movements. Perhaps the greatest single advantage she gained was what the teacher called the "aliveness" of her toes and feet in simple every-day activity. She also gained better social rapport in the group and improved her former obvious physical and mental queerness.

The therapeutic value obtained in the costuming is one of the factors of rhythmic dancing which will come more and more to be emphasized. It was very noteworthy as regards the nervous group here as a whole. The removal of several layers of clothing whose purpose seems to be to bind and hamper free activity, does much to put the dancer in rapport with the beauty of the nature setting; he seems to free himself physically so he might accept the freedom of the forest.

No small advantage in the rhythmic work was hinted at before it was derived in the reawakening of the dramatic play-instinct. The child-imagination was stirred again, and the later adult conflicts and self engrossment fell away. As the summer's work progressed the energy previously expended in neurotic conflicts was redirected into healthier channels. Coincident with this redirection of effort and power to control the will in a new line of conduct, was the noticeable improvement in mental concentration and control. At first this was brought out step by step by gaining power to listen to the music which was the accompaniment of the dance. Although this requires little mental effort, not one patient seemed to care whether his gestures were rhythmic or in time with the music. Indirectly, he gradually became aware that he was not an individualist engrossed in his own particular symptoms but that he was either a part of a glaring discord or an interpreter of a rhythmic motif of splendid beauty, a harmonious whole. Perhaps the dancer feels even greater rhythmic charm in music than the vocalist. At least our group seemed to suggest this view. Many expressed themselves as being made aware of the innate beauty of music for the first time in which rhythmic values were refined by bodily sensations and movements. While of course this value is but a part of all dancing, it seems to be developed most markedly by the freer system of rhythmic gymnastics.

Some photographs are incorporated as a part of this therapeutic work. It may be said contrary to what is usually the custom, no effort was made to pose the groups specially to gain unusual effects nor were the most proficient allowed to usurp the center of scenes to give the best exhibition possible. On the contrary the regular routine work is shown, good, bad or indifferent, as the plates may show.

My general opinion as to the lasting value of such a therapeutic remedy is that rhythmic dancing, especially outdoors in natural surroundings and modified for men patients, has come to stay, and should be more generally employed.

In conclusion I want to say that various new settings of mental therapy out of doors and in the country ought to be employed, not only for mild nervous disorders in private practice but in sanatoria and modern public institutions. Not a little advantage is gained in making these principles very flexible in application and as an integral part of country life. Properly equipped such an experiment calls out the very best initiative of teachers, nurses, and physicians. In my experience there are many values in the novel and bizarre not obtainable in systems and routines haltingly or indifferently applied. So long as we train neurotics for normal life interests

and the natural social activities that grow out of them, we cannot go far amiss in mental therapeutics.

For assistance in carrying out the general plan of work embraced in the summer school, I am indebted to Mr. T. E. Uniker, Miss Agnes Brill, Mrs. E. P. Whitney and Miss Mary B. Curtis.

20 West Forty-eighth Street.

ON SOME PRESENT-DAY CARDIOLOGICAL TOPICS.

By THOMAS E. SATTERTHWAITE, M.D.

NEW YORK.

For the last fifteen years many efforts have been made to devise suitable tests for cardiac efficiency, but opinions still continue to be divided as to their comparative usefulness. This matter, however, suddenly rose to be one of great practical importance at the outset of the war; while even now, presumably, the tests may at any time be necessary in determining the physical fitness of government employees. At the outbreak of the war they were used in the examinations of recruits to discover whether the men examined were fit for active service or not. A subsequent examination to test putative cardiac disability bore on the question whether the man could eventually be returned to active service or not. The problems were different. In the first, under prevailing circumstances, little time could be allotted for physical examinations and they were necessarily incomplete.[1-2] In the second, ample time was given for thorough examinations and the work was delegated to the men presumably best fitted for it, and they were furnished with the best appliances available. It is proper, therefore, to consider the two tests apart from one another, the former being only a preliminary one, as it were. Now, inasmuch as the accepted recruit was always under medical supervision, and could at any time be put under treatment in case of supposed cardiac disability, there was not the pressing need of a thorough examination as required in the second case. In the latter, however, the examinations were understood to be final, the men being in a position to receive all the tests that were available in the military machine, such as the following: [3] Trigeminal irritation by the inhalation of strong smelling salts that slow the normal heart but accelerate the neurotic. The oculocardiac elicited by pressure on one or both eyeballs. By this method the normal rate is slowed four to ten beats per minute. Any increased degree of retardation suggests trouble with the cardioneural mechanism. Again the administration of atropine, from 1/25 to 1/50 of a grain, increases the normal beat from 30 to 40 per minute, while in hearts with myocardial degeneration the increase may be only 20 beats or even less. These are the so-called neurological tests. The more important tests, however, depend on the reaction of the heart muscle to either active or passive exertion.

Selig's[4] has been very frequently used. The pulse and systolic blood pressure are taken before and after the subject climbs a flight of 20 steps. Normally there is an increase of 20 beats per minute and a rise of blood pressure of 8 mm. Hg. If the myocardium is insufficient, the pulse rate increases 30 or more beats, while the blood pressure rises more slowly, or falls. The length of time taken for the recovery to the normal systolic pressure may be regarded as the index of cardial efficiency.

The hopping-test,[5] the sole officially named government test, consists in having the patient hop twenty paces on one foot. It is a modification of the Selig test, but not so valuable as some others, inasmuch as the work performed cannot be computed accurately. Graüpner's[6] is better, as it consists in having the patient perform a more definite amount of work with a special instrument called the ergometer, and depends on a comparison of the behaviors of pulse rate and arterial pressure. In the normal heart under exercise the systolic pressure rises after the acceleration of the rate, and after rest is maintained, longer than in the inefficient heart where the pressure rise is both delayed and diminished.

Cabot and Bruce[7] have recommended using a measured amount of stair climbing, which is another practical and useful method. They estimated the amount of work in foot-pounds, which is computed by multiplying the number of pounds the individual weighs by the number of feet ascended. Thus an energy-index is provided.

Herz[8] has used simple flexion and extension of the arm and finds that in persons with weak hearts the rate increases five to twenty beats a minute.

Katzenstein's[9] test consists in compressing both femoral arteries. If the arterial pressure rises some fifteen mm. Hg. and the pulse rate does not rise, or even slows a little, the heart is held to be vigorous. If the pressure falls and the pulse rises in rate the heart is insufficient. I have used Schapiro's[10] method for about ten years.[11] The pulse is taken first in the recumbent and then in the sitting position. In health there is an increase of frequency, when the individual has assumed the sitting posture (after lying down), of from three to ten beats per minute. In the weak heart there is an absence of change or a diminution of the frequency in changing from the recumbent to the sitting position. This method is applicable for ordinary civilian practice. The three tests, however, that recommend themselves especially from their near approach to mathematical accuracy, if that is desirable, are those of Barach[12], Stone[13], and Tigerstedt.[14] The former takes the systolic pressure by a mercurial instrument, using the auscultatory method. The systolic pressure gives the energy-factor of the heart, the diastolic, the energy-factor of the peripheral resistance, while the two combined give the energy-index of the entire circulatory system. Now, if these two are multiplied by the pulse-rate, the sum represents the total cardiac energy used in one minute. This should be compared with the average systolic and average diastolic pressures, multiplied by the normal pulse rate as shown by the ordinary tables and the result will indicate the degree of variation in the abnormal heart energy from that of the normal heart. For instance, if the pulse rate were 72, the systolic pressure 120, and the diastolic 70, the result would read as follows:

Systolic Pres.	120 mm. Hg. $\times$ 72 =	8,640
Diastolic Pres.	70 mm. Hg. $\times$ 72 =	5,040
Total		13,680

which last figure would represent the total of normal energy spent in one minute. Any higher figure than this would represent a proportionate increase in energy; any lower figure a corresponding loss in energy. By this plan the energy is represented in plain figures.

Stone's index of efficiency is even more simple. He estimates it by dividing the pulse pressure by the diastolic. Testing it in 400 cases, he found that while the normal is set at 50, there was less than 1 per cent. of variation in his cases. His index is: $\frac{\text{P.P.}}{\text{D.P.}}$ In Tigerstedt and Strassburger's test the index is derived from four factors. Multiply the pulse pressure by the pulse rate and divide the result by the systolic pressure multiplied by the pulse rate, and the formula reads: $\frac{\text{P.P.} \times \text{P.R.}}{\text{S.P.} \times \text{P.R.}}$ While the average normal quotient is 33, by this method normal cases register between 30 and 35. These methods recommend themselves for their simplicity, and because the index of energy in each is expressed in numerals. They are adapted for the examination of invalided men in service, when being tested for cardiac efficiency. Bernard Smith[15] has also published some statistics following an examination of 500 applicants for the aviation service, of whom 400 were accepted. His conclusions were, however, that the various blood pressure findings alone were of little absolute importance in determining physical fitness for aviators, but that with the added information derived from the results of measured exercise the results were of definite value. He adopted the Selig method of stair climbing, the stairs being 24 in number, each with a 6-inch rise, the time consumed in the ascent being five seconds. He estimated the measure of efficiency by the Tigerstedt-Strassburger formula, using the auscultatory method of determining the pressures.

The tests by the injection of atropine and epinephrin, and by compression of the femorals, however, are suggestive of animal experimentation and the physiological laboratory. They will probably be unpopular with many in civilian practice for this reason. Besides, most of us do not care to inject strong drugs for diagnostic purposes, and in the case of epinephrin, especially, one that is not always safe, as I have taken occasion to state on another occasion.

In the matter of testing cardiac efficiency whether in government service or out of it, we must realize that absolute accuracy in finding its degree will not be and cannot be reached. Our accuracy can be only relative. We neither have a normal energy-index, nor can we get one. Each individual has his own index just as each has his own thumb mark. The index will vary with him, according to his psychic state, his age, weight, and height, his position when examined, the external temperature, the quality of the atmosphere, and other conditions.

One of the minor points of interest that has been evoked by the use of mercurial manometers is that from the oscillations of the column in the tube a diagnosis of alternating pulse can be made by the naked eye (Kilgore[16]). This is a point of some value.

That it is important to take the pressures in both arms has been shown by Bowers.[17] In a study of 31 patients between the ages of 65 and 95 he has found that there is sometimes a considerable difference between the two sides, particularly in arteriosclerosis. He also believes, as the result of his studies, that a high pressure in these cases points toward cerebral hemorrhage; a low pressure to cerebral embolism. This matter calls for further investigation.

In a case now under my care, of a young lady who had an attack of cerebral embolism (or possibly hemorrhage) some years ago, but who has recovered so that the mobility of the affected (right) side is nearly restored, she had no pressure on the right side, when first seen by me, that could be registered by my manometer. Also there may be a difference in systolic pressure between the two sides of as much as 20 mm. Hg. (Cyriax[18]). The same is true in unilateral tuberculosis. The rise in the pressure is on the affected side.

Fortunately, as Anders[19] and others have pointed out, there has been a tendency of late to emphasize the fact that hypertension is misunderstood. Yet it is true that regardless of its cause it has an unfavorable outlook. It suggests renal difficulty or arteriosclerosis, but may be due to a neurosis; to excess in eating or drinking; to an idiosyncrasy; or to a familial peculiarity. Besides, it may be physiological. The first examination may show high pressure; the second a notable decrease in the pressure. These facts should be constantly borne in mind in making a prognosis. And yet, as I have intimated, high pressure must always be taken seriously. It does not, as a rule, suggest longevity, but there is every reason not to alarm the patient, in any case. As these facts have not been generally known, the unfortunate patient's condition has sometimes been jeopardized, from fear of a stroke, perhaps, when there was really insufficient cause for alarm. Nor is hypotension well understood.

A good deal of attention has been given, of late, to what was called at the time of our Civil War the "soldier's heart" and later "Da Costa's irritable heart." Wilson and Mackenzie,[20] however, admit it was discovered by Henry Hartshorne of Philadelphia, in 1864 (see *Am. Journal of the Med. Sciences*, July 1, 1864), and that the criteria he gave are the same as those of the "irritable heart" of to-day, viz., "great exhaustion after effort, breathlessness on slight exertion, a rapid pulse, which becomes more rapid upon the slightest attempt at action, pain over the cardiac region, or along the left costal region, and a vasomotor condition of greater or less stability." Wilson's experience was derived from a study of 200 "irritable hearts." This much, however, should be added to the history of the "irritable heart." When, in 1864, Hartshorne described it before the College of Physicians of Philadelphia, he stated that Alfred Stillé had recognized it, the year before, after a study of 400 cases.

Sir James Barr[21] has claimed that it is a thyroid disorder. Carroll[22] has called attention also to similarities between the symptoms of the irritable heart and thyroidism, saying that in both there is hyperactivity of the opposing nerve fibers of the autonomic system; but he has taken the ground that in both there is a constitutional predisposition owing to sympathetic or vagotonic instability, the remote causes being chronic infections of some sort.

Meakins[23] holds that the "irritable heart" is not a pathological entity, and is not strictly a "soldier's heart." He gives the symptoms, as he has noted them. There is at first a rise of blood pressure but only if the patient is up and about. Then it remains high longer than usual. Left precordial pain is common, but increases during an intercurrent affection. Orthodiagraphic methods show no increase in the heart's area, which may even be diminished. The rate of respiration is always at the upper limit of normality, but during sleep it is seldom below 20 as against a normal of between 8 and 14. In several cases of the "irritable heart," the rate in sleep may rise to 40 or 50 per minute. After exercise the rate always increases. These patients show some degree of nervous irritability. There may be tremor and giddiness. Many of them have a personal or family history of a psychoneurosis, and in 70 per cent. he found constitutional asthenia. An increase of red blood cells is credited to the respiratory disturbance. There is always a rise in the leucocyte count. It may reach 12,000 or even 15,000. There is also a high lymphocyte count, which may vary from 25 to 75 per cent. of the total count. There is a relative acidosis due to a deficient aeration of the blood caused by the shallow breathing. The "irritable heart" is, to his mind, a conglomerate of functional disturbances, rather than a pathological entity.

In a very elaborate account of the "irritable heart" Neuhof[24] concludes as follows: The irritable heart as observed in general practice is similar to that found in soldiers. Vasomotor symptoms are more pronounced in the former. The etiologic factors are similar, but because of training and war conditions, dormant and latent neuroses crop out oftener and are more readily evoked; consequently the cardiac syndrome is more violent and lasts longer. Infection is a factor only in so far as it induces and produces nerve and muscular fatigue and psychasthenia. There is no specific pathological change in the cardiovascular system. The fundamental cause of the cardiac neurosis with its various manifestations seem due to hyperexcitation of the sympathetic nervous system.

Warfield and Smith,[25] in writing of it among men being inducted into service, say a diagnosis of the condition may be made by taking a careful history, paying particular attention to previous attacks of dizziness or fainting or exhaustion, precordial pain, and pounding of the heart on *slight exertion;* second, by noting the unusual physical response to the hopping exercise and an increase in the pulse rate out of all proportion to the exercise.

From a survey of these views we see that there is some lack of uniformity as to the special diagnostic features of the "irritable heart." The reason is that it represents a conglomeration of morbid states differing from one another in many respects, but still having similarities that admit of its diagnosis. It it not, however, a pathological entity nor is it a "soldier's heart." It is seen in civilian life as well, but it is well to classify it, temporarily at least, under a special name, and there seems to be no good reason for calling it anything but the "irritable heart."

The rôle of infective agents in producing heart disease has been established in many instances. In rheumatism, scarlet fever, and measles, we accept the theory that these affections may have associated with them endocarditis, which in many cases is a phase of the malady. We have also constantly before us claims that the meningococcus of cerebrospinal fever, the bacillus of influenza, and the *Streptococcus viridans* of oral sepsis are causes of endocarditis. But we are confronted with the statements of Rosenow, if he has been correctly quoted, that a streptococcus of the mouth or tonsils may change into the germ of pneumonia and back again on to a micrococcus, and that a simple innocent variety can be converted by culture into an infecting agent, morphologically different and capable of producing many different diseases. These statements are certainly amazing, so that we must in justice to preconceived notions wait for further developments before we can accept them.

Cecori[26] has reported a case of "slow endocarditis" in which the disease began with a gallstone cholecystitis associated with an irregular but slight fever, that lasted over five months and terminated fatally. At the autopsy colon bacilli were found in the gallbladder, while there was a small colony of streptococci in the heart walls and valves.

Since Babcock[27] called special attention in 1919 to chronic cholecystitis as a cause of myocardial incompetence, the attention of both physicians and surgeons has been specially directed to this interrelation. Babcock has published 13 cases, of which he made four groups: (1) where there was cardiac decompensation with murmurs, dilation, arrhythmia and feeble heart action; (2) where there were attacks of pain that were anginoid in character, or infracardiac and were followed by symptoms of cardiac inadequacy; (3) arrhythmias that were very intractable, and (4) valvular diseases in which there was cardiac incompetence evidently produced by hepatic colic.

Discussing this matter, he has called attention (1) to the well known disastrous effects of acute cholecystitis on the heart, setting up, as he believes, a myocarditis, acute or chronic; (2) to the depressing effects of cholemia on the heart by the biliverdin, and the increase in blood pressure, due to bile-salts; (3) to the possibility that an irritation of the splanchnics, which are the regulators of the circulation, is the cause of the trouble; (4) to the irritation of the pneumogastric terminals, which are distributed in the wall of the gall-bladder and act reflexly on the heart. In such instances as these the importance of an early opening into the gall-bladder and drainage is emphasized. In this connection the question of merely draining the gall-bladder or removing it has been discussed by C. H. Mayo.[28] If there is no active infection and the integrity of the organ has been maintained, drainage will give relief, he says, in a high percentage of cases; otherwise removal of the gall-bladder is to be recommended.

In the case of a patient who was under my care in 1916, and who had been treated medically three times in Carlsbad for gall-bladder trouble, there was pain about the heart and arrhythmia, with recurring attacks of gallstones, colic, and perihepatitis. An operation was deemed advisable, but was deferred, as usual, until the acute symptoms had subsided. Cholecystectomy was then done. The

patient passed from under my care, but the result was satisfactory, at least in so far as that the heart symptoms were temporarily relieved. Recently, I am told, he succumbed to the heart trouble. An earlier operation in this case would, in the light of his history, have been desirable.

From the above views we may assume that cardiac decompensation is due to chronic gall-bladder disease as well as to the acute form.

While the fluoroscope and the *x*-ray have now been used for many years in the diagnosis of aneurysms, especially the thoracic, their uses in the determination of circulatory disorders have been less conspicuous in their application to the heart. Hirsch,[29] however, has demonstrated that these methods will define the contours of the heart satisfactorily even in pronounced pulmonary emphysema, when the cardiac dullness cannot be elicited by percussion and when the apex cannot be located by either percussion or auscultation. By such methods the contour of each auricle or ventricle can be made out, and their relations to the great vessels at the base of the heart. It is improbable, however, that the *x*-ray will give much assistance in the localization of valve diseases, or that any form of contour can more than suggest the pathological condition of a valve. And yet it is claimed that there are more or less distinctive features of valve disease shown by the *x*-ray. At any rate, whether the fluoroscope or the *x*-ray is used the examiner should always be provided with pictures of the normal heart, so that one can differentiate its contours from those of the diseased organ.

By these methods, also, the infantile heart can be demonstrated, as Bishop[30] has shown.

The *x*-ray picture is useful in that it is taken at a standard distance from the patient, viz., 6 feet, while it shows the bony framework of the chest and both the anterior and posterior arches of the ribs. In this way the relation of the base of the heart to the anterior ribs is shown. In addition, by means of Bardeen's tables, we are now furnished with the normal size of the heart, according to the age and weight of the individual and so can detect any variation from the normal contour, which can also be sketched on the plate over the heart's shadow. Further by the planimeter the actual dimension of the heart can be measured. Both the fluoroscope and the *x*-ray furnish direct proof of abnormalities, but the latter makes a permanent record of it.

In the matter of drugs the advantages of digitalis have come more and more to the fore. At the same time, however, its modus operandi is quite commonly misappreciated, as well as the vast differences in action between its various preparations.

Digitalis absolutely controls fibrillation and flutter, temporarily at least, if used in appropriate doses. Unfortunately, there seems to be good reason to believe that in the recent pneumonias of the influenzal epidemic it was given in excessive doses. Digitalis is a two-edged sword. It may restore to life, in the most amazing manner, when death seems to be at hand. On the other hand it may produce heart block, and kill if it is given without due comprehension of its modus operandi. Digitalis may take 36 hours or even more before any effect on the system is noted. If during this time the administration of it is persisted in, the action will be cumulative and the result fatal perhaps, provided the particular preparation of the drug is active. Some of the preparations now on the market can be relied upon to be up to the standard; others may be practically inert.

I am pleased to be able to say now, contrary to impressions produced by some experiments of the late Boos[30] that digipuratum in the ampules, each containing 1 c.c., can be given safely by deep muscular injection with satisfactory results, even though the system, at the time, is saturated with digitalis. That is, the full of the ampule containing 1 c.c. can be given without necessary dividing the dose. Under these circumstances, I usually allow an interval of two or more days between the injections. Though I have given it occasionally in daily doses, with good effect, it may be well to divide the doses until we have gathered more information on the matter. In my opinion, however, there is no remedy that produces such prompt and satisfactory results in extreme heart failure, as the liquid digipuratum, given in one dose by deep muscular injection. In this connection it may be well here to notice the remarkable case reported by Mollison[32] where a young boy developed heart failure during the operation of tonsillectomy. Artificial respiration having failed, an incision was made from the ensiform to the umbilicus. Through the opening thus made, the heart was exposed. One c.c. of pituitrin was then injected into the heart substance. A saline infusion was also given. The anesthetic used was composed of chloroform, two parts, and ether, three parts. The boy recovered, but unfortunately the query still remains unanswered, To which particular agency was the recovery due?

In the matter of prognosis, the early fatality of pulsus alternans has been studied by White,[34] as also that of auricular fibrillation, when complicated by abnormal ventricular reflexes. In both death may be anticipated within three years. On the other hand, in uncomplicated auricular fibrillation the danger to life is comparatively small.

Nothing has developed in medical circles within the last few years that promises greater benefit to the public, our profession generally, and the cardiologist in particular, than the scheme of having what has been called "group diagnoses." While this plan had been carried out for more than a quarter of a century in the wards of some of our large hospitals, it did not rise to the dignity of a regular feature of an institution, so far as I know, until it was adopted by the Manhattan State Hospital for the Insane, on Ward's Island, in or about 1902, where complete diagnoses were made in every case admitted by a staff of paid specialists. The present scheme has three or four diagnosis clinics in operation in Greater New York. Examinations and reports are made for physicians only, in each special department, and the combined results are furnished, together with the essential points in each case. Up to this time physicians in general have had for the most part no hospital opportunities. For them these new institutions offer their patients the help of trained specialists at a minimum cost to each. Without such helps many physicians must be forever groping about in the dark, unable to make up-to-date diagnoses, from lack of either experience or appliances.

An out-of-town surgeon, not connected with any well-equipped hospital, is confronted with a possible operation for exophthalmic goiter. It is a case for a surgeon or internist, but which? Nor can a decision be reached without a series of examinations of the patient by specialists. He applies to a Diagnostic Clinic and a report is sent him covering all the points in the case necessary to make his course clear.

A surgeon friend of mine was confronted with such a case. Experts along various lines examined his patient and as a result an operation was felt to be contraindicated, and the patient was turned over to an internist. The same course of action holds good for the general practitioner, and especially one who is far away from a great medical center. Under this plan the patient may be sent to one of the clinics and returned to his own physician with definite statements as to any course of treatment which is thought proper by the several specialists to whom he has been sent. Valuable time is saved, perhaps thereby the patient's life. In fact, one may make the broad statement that thorough, comprehensive examinations can no longer be made by either specialists or general practitioners without help from their confrères.

The field is now so large that no one man is competent to cover it properly. Therefore diagnostic clinics, with "group diagnoses," have come and are going to stay. The cardiologist appreciates this fact as much as any other specialist.

INTERESTING CASES FROM THE ORTHOPEDIC CLINIC OF LEBANON HOSPITAL.*

BY JACOB GROSSMAN, M.D.

NEW YORK.

CHIEF OF THE ORTHOPEDIC CLINIC LEBANON HOSPITAL; CHIEF OF THE ORTHOPEDIC CLINIC STUYVESANT POLYCLINIC; INSTRUCTOR OF ORTHOPEDIC SURGERY NEW YORK POST GRADUATE MEDICAL SCHOOL.

WHILE the following cases are not only of rare occurrence, they also present interesting features which warrant this report.

The first case is that of a woman who had fallen down a flight of stairs and had sustained a double Colles' fracture. This is the first case of double Colles' fracture which we have seen in a fairly active fracture clinic. Unlike the usual manner in which Colles' fracture is produced, that is a fall on the outstretched hand, this patient fell and landed on the dorsum of her hands, the hands being in flexion. The history of the case follows:

FIG. 1.—Case I. Fracture of left radius.

CASE I.—Mrs. N., age 39. Tripped and fell down a flight of stairs, striking upon both hands, which were in flexion.

Examination: The usual signs of fracture of the lower end of the radius were present. The right wrist was also very tender in the region of the styloid process of the ulna.

Diagnosis: Double Colles' fracture, with fracture of the styloid process of the right ulna. This diagnosis was confirmed by subsequent *x*-ray pictures (Figs. 1 and 2).

Treatment: Immobilization with plaster of Paris bandages, followed by early baking, massage, and exercises. The patient made an uneventful recovery, with good function in both wrists.

*Cases presented at a meeting of the Lebanon Hospital Alumni Society.

The following cases represent a type of fracture which is commonly overlooked, because the cardinal signs of fracture, namely crepitus, false mobility, and deformity are usually lacking. It is very commonly found in children. The usual site is the

FIG. 2.—Case I. Fracture of right radius and styloid process of ulnar.

tibia, only one case having occurred in the fibula in quite a series of cases. These fractures are incomplete and are known as subperiosteal or intraperiosteal fractures. The most constant and what can be designated as the diagnostic sign, is the localized bone or "pencil" tenderness. The way to map out this maximum point or line of tenderness is to palpate or make pressure with the back of a pen or the rubber tip of a lead pencil. By tracing the point of maximum tenderness one can in a vast majority of cases trace the line of fracture. We have confirmed our clinical findings with *x*-ray pictures, one of which is shown in this report. (Fig. 3). This tenderness is at times very exquisite. Many parents are surprised to learn that their children had sustained fractures, so trivial had been the suffering both subjectively and functionally. The diagnosis is made by tracing the line of maximum tenderness. The duration of this sign varies, sometimes persisting for months.

The following history is typical of a fracture of this type.

CASE II.—Julius F. a few days before being brought to our clinic, fell, striking upon his leg. No attention was paid to the accident as he was able to get about. For the following few days the child complained of pain only when he walked.

Examination: The patient walked with a slight limp. The leg was swollen, there was no deformity, ecchymosis, crepitus, or false mobility. A line of tenderness was traced along the shaft of the tibia for a distance of two and a half inches.

Diagnosis: A diagnosis of subperiosteal fracture of the tibia was made and proper treatment instituted. A subsequent *x*-ray picture confirmed the diagnosis (Fig. 3).

Treatment: The treatment of this type of fracture differs only from that of complete fracture in that the period of immobilization is of shorter duration.

Fracture of the head of the radius occurs more commonly than was formerly believed. It is usually the result of a direct injury and occasionally results from an indirect injury, such as a fall upon the outstretched hand.

The head of the radius is very prone to fracture on account of its exposed subcutaneous position. The head is readily palpable and can be felt rotating at the radiohumeral joint. When the patient falls, striking upon the outer side of the elbow, the head of the radius is compressed between the ground and the coronoid process at the lesser sigmoid cavity, with the result that the tangential portion of the head is cracked off. Occasionally a stellate comminuted fracture may result. The external epicondyle of the humerus may also be the site of a chipping fracture. When the fracture results from indirect violence the head of the radius is jammed against the capitellum.

The chief sign of this type of fracture is a wincing tenderness, elicited by direct pressure upon the head or neck of the radius. There may be swelling opposite the radiohumeral joint, due to effusion from a traumatic synovitis. Pain may be produced by rotating the forearm. Ecchymosis may appear late and is usually found below the radiohumeral joint. Fracture of the head or neck of the radius may be accompanied by luxation of the elbow, fracture of the external epicondyle, and occasionally by injuries at the wrist.

A very interesting condition which should be borne in mind when making a differential diagnosis between the various elbow injuries is that known as traumatic palsy of the forearm. It is very common in children. It is one in which a partial dislocation of the head of the radius results from a trauma to the upper extremity. The history of the trauma and the subsequent picture are characteristic. The patient has been dragged along or raised by the wrists, following which there is disability and severe pain when manipulation of the affected extremity is attempted. The limb hangs limply at the side as if the case were one of flaccid

FIG. 3.—Case II. Subperiosteal fracture of the tibia.

paralysis. Naturally the possibility of a fracture at the elbow must be considered. Slight swelling at the elbow may be present. Ecchymosis, crepitus, deformity, and false mobility are absent. Passive flexion and extension are not restricted. Prona-

tion and supination are limited. Upon extreme supination a clicking sound is heard, at which time the head of the radius slips back into its normal position. Immediately thereafter there is resumption of the normal functions of the limb. This condition is by no means uncommon and should always be remembered when diagnosis of elbow injuries is made.

The treatment of fracture of the head or neck of the radius is the same which obtains in the treatment of intraarticular fractures in general. One must remember that the head of the radius lies wholly within the joint, is covered with synovial membrane and bathed by synovial fluid. Hence fracture of the head of the radius is usually accompanied by traumatic synovitis and some hemorrhage within the joint. In view of these facts the best treatment is immobilization with early baking. Movements should be delayed until the swelling of the radiohumeral joint has subsided. In selecting an immobilizing agent, one must remember that the head of the radius enters into the formation of two joints, the radiohumeral and the radioulnar, and the fixation agent must control both these joints. A very simple and efficient fixation agent is one which maintains the forearm in acute flexion. The bare forearm is fully flexed so that the hand on the affected side rests on the opposite shoulder and the elbow is carried well forward on the chest. The position is fixed by a strip of adhesive plaster encircling the arm and forearm just above the elbow joint. The forearm is now bandaged to the arm by figure-of-eight turns of a flannel bandage. Before applying this dressing the arm should be dried and powdered and boric acid cotton placed in the elbow crease and the axilla to absorb the perspiration and keep the parts dry. The limb is retained in position by a sling around the neck.

Immobilization should be continued until the swelling disappears. Baking should be begun immediately and continued daily throughout the treatment. Passive movements followed shortly by active movements should be begun as soon as the swelling has subsided.

In case a fragment has been separated and become displaced, so as to block flexion of the forearm and it cannot be reduced by conservative manipulation, operative measures should be instituted and the offending fragment either replaced in the proper position or, in old fractures, removed. The following history is representative of a series of seven cases of fracture of the head and neck of the radius which we have seen.

CASE III.—Pearl D. slipped and fell downstairs a distance of four steps, landing upon the outer side of her elbow.

Examination: There was slight swelling at the radiohumeral joint, no ecchymosis. There was no displacement of any of the three processes. There was excruciating tenderness over the neck of the radius. Flexion and extension of the elbow was free and painless, pronation and supination were painful and restricted.

Diagnosis: A diagnosis of fracture of the neck of the radius was made and proper treatment instituted. A subsequent *x*-ray picture confirmed the diagnosis.

Fracture of the great tuberosity of the humerus does not occur very frequently. In this type of fracture the great tuberosity may be detached without any loss of continuity in the shaft of the bone. This accident gives rise to considerable broadening of the shoulder, the fragment being drawn upward and backward by the muscles attached to it. The continuity of the head of the bone with the shaft is unimpaired. The fragment in the following case was not completely detached and was firmly held in position by untorn bands of periosteum. The position most favorable for good union is in abduction and outward rotation. The following case is one of three which we have seen. In one, fractures of the surgical neck of the humerus and outer end of the clavicle were also present. The other one was similar to the case to be reported.

CASE IV.—D. N. fell, striking upon her shoulder. Came to the clinic the following day complaining of pain and disability of the shoulder.

Examination: The arm was held in adduction and supported by the other hand. There was swelling about the shoulder and ecchymosis covering the lower two-thirds of the arm. There was a distinct widening of the shoulder joint. There was no deformity. All the movements of the shoulder were restricted and attempts at passive movement were very painful. There was excruciating tenderness over the upper part of the humerus in the region of the great tuberosity.

Diagnosis: A diagnosis of fracture of the great tuberosity of the humerus was made and proper treatment instituted. A subsequent *x*-ray picture confirmed the diagnosis. The patient made an uneventful recovery.

The following case is one of a double birth palsy. While single birth palsy is not uncommon, double birth palsy is rarely encountered. It is usually the result of an injury to the nerves of the brachial plexus. The resultant paralysis is characteristic. When seen early the arm hangs limply at the side. Later the elbow becomes flexed, the forearm pronated and the entire upper extremity inwardly rotated.

It is evident that the paralysis is due to forcible separation of the head and the shoulder, resulting in a tear of some of the cords of the brachial plexus. There are two well recognized types of paralysis seen. The more common consists of a lesion which involves the fifth and sixth cervical roots and the suprascapular nerve. This type, known as the upper arm type, produces a paralysis of only the muscles of the upper arm, with the exception of the supinators. The other type, known as the lower arm type, results from the injury not only of the fifth and sixth cervical roots, but also of the seventh and eighth and possibly of the first thoracic. The entire upper extremity is flaccid, there is a wrist drop with paralysis of the small muscles of the hand. In the milder cases the stretching or tearing force results in a hemorrhage or edema into the nerve sheaths. In others there may be a rupture of the perineural sheath accompanied by hemorrhage into the substance of the nerve trunk, with or without tearing apart or a separation of the nerve fibers. In the severer cases there is either a partial or complete division of the fifth and sixth cervical roots.

The early picture of the upper arm type is classical. The arm hangs limply at the side, slightly flexed, and rotated inwardly. There is complete inability to abduct, elevate outwardly, or supinate the upper extremity. There is absence of active flexion at the elbow. In the lower arm type in

addition to the above, there is paralysis of the forearm and the hand. Wrist droy, inability to supinate and extend the forearm are usually present. Paralysis of the flexors and extensors of the fingers, associated with paralysis of the small muscles of the hand, is often present. The proximal phalanges may be hyperextended and the distal ones flexed, due to a paralysis of the interossei or lumbricales.

The treatment of birth palsy resolves itself into expectant and operative. The upper arm type usually responds to massage, exercises, and a brace. The lower arm type as a rule has to be operated upon. Unless the treatment has been instituted early in the former, operative interference becomes necessary. This operation is not for repair of the plexus, but to correct contraction deformities.

To prevent these contraction deformities it is well to maintain the arm at rest in a position where the unparalyzed muscles cannot become contracted. This is best accomplished by the use of a wire splint which will retain the arm in an abducted, elevated, and outwardly rotated position, with the hand in supination.

Massage and exercises are of the greatest importance and should be practised daily. This treatment should be continued for several years, and if contractures develop in the subscapularis and pectoralis major, they should be divided before any further range in the arm is to be hoped for.

Regarding operation on the plexus—it is best to operate early, the earlier the better. The operation comprises repair as far as possible of any injury or damage to the nerve roots that may be met with. The after care is similar to that recommended above, *i.e.* prevention of deformity, massage, and exercises.

The prognosis in all upper arm types is good, provided treatment is carried out properly and early enough. In the lower arm type the outlook is not so favorable. The upper arm may recover

FIG. 4.—Case V. Double birth palsy. right side has completely recovered; brace on left side to maintain abduction and external rotation.

but the forearm and hand remain paralyzed. Treatment should nevertheless be carried out over a long time.

CASE V.—Baby F., 9 months of age, first child, breech delivery. One week after birth the mother noticed that both upper extremities hung limply. The infant made no attempt to move either of them. As soon as the mother was able to, she brought the child to the clinic.

Examination: Examination disclosed a typical birth palsy (upper arm type), with adduction of the arms,

FIG. 5.—Case VI. Syphilitic osteoperiostitis of the humerus.

flexion at the elbows and inward rotation of the upper extremities.

Treatment: The treatment consisted of massage and retention of the arms in a position of rest, by means of braces (Fig. 4).

Subsequent course: At the age of nine months there was complete recovery of the right arm and almost complete recovery of the left. The left arm can be abducted to an angle of almost one hundred degrees.

In all suspected cases of syphilis of bones and joints it is essential that we go into the family and personal history of the patient, bringing out a complete history of the parents as chronic rheumatism, various eye troubles, chronic bone suppurations, miscarriages, sterility, sudden deaths (apoplexy), as well as a definite history of the primary infection in either parent. In the personal history of the patient in congenital syphilis we should look for such symptoms as rhinitis, lesions of the skin and mucous membranes, iritis, suppurating lesions of the hands and feet, malnutrition, and dental changes such as Hutchinsonian teeth, dental interspacing, fluting of the incisors, and humpy molars (Roberts).

In acquiring syphilis it is not always possible to obtain a definite history. In these cases one must not overlook the fact that in any suspected case a Wassermann should be made.

The onset of the symptoms is generally insidious with frequent relapses. In a number of cases it follows a definite history of trauma. Pain is one of the main symptoms complained of. It is very severe and worse at night. Swelling may be present. Tenderness, localized to the area involved, is also a fairly common symptom. The *x*-ray findings may show a periostitis, osteitis, or an osteochondritis.

CASE VI.—Chas. S., age 42 years, white, American, married eighteen years.

Wife had two miscarriages and one still birth at the seventh month. Four living children, apparently well.

History of a chancre twenty-two years ago, for which he had received two months' treatment, which was medication taken by mouth. Present trouble began about three years ago when while swinging a heavy hammer, he felt something snap in his right arm, at the same time his arm falling limply to his side as if it were paralyzed. He went to a hospital where an *x*-ray showed a supracondyloid fracture of the humerus. His arm was immobilized. In spite of this immobilization the pain persisted. After several months' treatment for the fracture he was discharged, still having pain, worse at night. He applied home remedies and liniments for this pain, without relief.

He then went to another clinic where his blood was examined and it showed a four plus reaction. During the course of four months he received twelve injections of salvarsan, but no internal medication, without any relief of the pain.

In June, 1919, he came to our clinic, complaining of excruciating pain in the arm and disability, so severe that he was unable to work.

Examination: At this time his arm showed marked tenderness and thickening of the lower two-thirds of the right humerus and limitation of motion in the right elbow. His pupils were irregular, unequal, and reacted sluggishly to light. A blood Wassermann was made and it showed a four plus reaction. An *x*-ray picture (Fig. 5) showed an osteoperiostitis of the humerus.

Treatment: He was placed on mixed treatment consisting of mercury intramuscularly once a week and the iodide of potassium by mouth. In three weeks his pain had subsided and a few months later he was well enough to return to work.

The following case is one of several of infantile paralysis which were overlooked at the onset and came to our clinic a number of years later for advice. The mother of this patient was surprised to learn that her child had an attack of infantile paralysis, as she could not recollect the child ever having been paralyzed. The distribution of the paralysis is an unusual one and occurred infrequently during the last epidemic. The small muscles (thenar muscles) of one hand and the calf muscles in the opposite leg were the groups paralyzed. The history follows:

CASE VII.—K. S., 11 years of age, second child, normal delivery. At the age of twelve months when the patient began to walk, the mother noticed that the left foot turned out. She went to a clinic, where she was told that the child would outgrow the condition. The mother always noticed that one limb was thinner than the other. Four years ago (1915) she came to our clinic on account of pain in the left heel, and a limp.

Examination: The child walked with a limp on the left side, and there was distinct atrophy of the left leg. All that remained of the tendo Achilles was a very thin cord. The thenar prominence of the right hand was absent. The right thumb could not be adducted.

This is undoubtedly a case of poliomyelitis involving the calf muscles of the left leg and the thenar muscles of the right hand, a rather unusual distribution of paralysis.

These cases have been chosen at random from the records of the Lebanon Hospital Orthopedic Clinic, not only for their rarity, but also for the interesting features which they present.

1051 BOSTON ROAD.

Antagonism of Adrenalin and Quinine.—Clerc and Pezzi speak of the subtotal antagonism between these substances. Thus adrenalin excites the center of the vagus in the bulb while quinine paralyzes it. One drug therefore excites the heart and the other slows it. Similar antagonism is seen in the province of the blood pressure, but here the activities are complex: adrenalin raises the tension by combined cardiac and vascular action, and quinine makes for hypotension by a mechanism which is not altogether obvious. Both drugs are technically vasoconstrictors.—*Le Progrès Médical.*

HIPPOCRATIC MEDICINE.*

BY JOHN H. HARE, M.D.,

EVANSVILLE, IND.

IN presenting this paper to a body of men, supposedly strictly scientific, I feel it necessary to offer some apology for consuming our time with an historical subject. If I may be allowed to quote in advance from my author I may give one reason in his words. He has written, "The physician must know what his predecessors have known, if he does not wish to deceive both himself and others." We certainly should be familiar with the writings of the greatest physician.

Francis Adams, a surgeon of a small village in Aberdeenshire, has given us the best English translations of the Greek classics that we have and has thereby made a world name for himself as a scholar. It is from his translation of the works of Hippocrates, published by the Sydenham Society, that I draw my material for this paper.

For our purposes of discussion we may, more or less arbitrarily, divide the history of medicine into three periods. We may call these: first, the mystic period; second, the period of humoral pathology; and third, the modern or bacteriologic period. The first period extends from the beginning of things to near the time of Hippocrates and is characterized by the mysticism accompanying, or forming rather, the practice of medicine. About the time of Hippocrates some theories of pathology were being formed in an attempt to explain disease processes. Although in the light of modern knowledge these theories are ridiculous, they represent the first attempts at seeking the truths of nature and the true beginning of scientific medicine. Of the modern period it is scarcely necessary to speak; the most valuable parts of it have been developed within the memory of men now living.

The period in world history during the fifth and sixth centuries before Christ marked the zenith of Greece in all her activities. Her wars with Persia had terminated in great conquests, her art had reached the highest development the world has ever known; the philosophy of Plato, the learning of Pythagoras are equaled only by the medicine of Hippocrates. The time was ripe for the birth of such a genius. The collection of invalids at the Asclepidæ provided the clinical material and the writing, imported from Phoenicia, provided the means of expression and record.

These Asclepidæ are worthy of note. They were originally built for temples in which to worship Æsculapius, the god of health, and quite naturally developed into hospitals or sanitariums. The teaching of medicine took place at these temples, and the physicians were priests to the god of health. The system of teaching in a hospital we recognize now as the best method and it is only in the past few years that our own medical schools have realized the wisdom of this and now, after more than two thousand years, are building their own hospitals. It has been estimated that there were sixty-four of these Asclepidæ throughout Greece at the time of Hippocrates. However, two, those at Cos

*Read at the twentieth annual session of the Ohio Valley Medical Association at Evansville, Ind., on November 11 and 12, 1919.

and Cnidos, easily ranked above all the others in popularity and in personnel of staff. The characteristics of these two are summed up admirably by Dr. Theodore H. Allen in his "Brief History of Medicine" as follows:

The school of Cnidos is said to have laid especial weight upon the subjective statements of the sick, the relation of the symptoms to individual parts of the body, and the use of active remedies, especially drastics. Less attention was devoted to diet. It cultivated the science of diagnostics and recognized some auscultatory signs, *e g.* the pleuritic friction sound, and it satisfactorily distinguished many diseases, such as phthisis, typhus, disease of the urinary bladder, the kidneys, the bile, etc. The Cnidans also performed even major operations, like trepanning the ribs and excision of the kidneys, and though always empirics they were bold operators. In opposition to the physicians of Cos, however, they discarded venesecton.

The school of Cos (which was flourishing as early as 600 B. C.), in contrast to that of Cnidos, cultivated especially objective investigations, symptomatology, prognosis, the relation of symptoms to the entire body, etiology, and expectant and mild therapeutics, though it recommended venesection; in short, it practised all that is worthy of praise in the medicine of Hippocrates and the Hippocratists. These two schools are the first examples of those two opposing tendencies which have characterized medicine down to the present day.

The generally accepted date of the birth of Hippocrates is 460 B.C. There is, however, very strong evidence that this should be farther back, possibly to 480 B.C. But for practical purposes it is well established that he practised the latter part of the fifth century before Christ. His father was a physician of Cos, so was his grandfather; and according to more or less mythical genealogy, his ancestors are traceable back to Æsculapius himself. Thus he was born and spent his early youth in one of the most famous hospitals of the age and had the opportunity of observing medical practice from the beginning of his life. Not very much more is known of his life except that he visited, in the course of his practice, a great many distinguished personages and traveled very widely. The story is told that he had to leave Greece because he had burned the library at Cnidos in order that he might have control of all the medical knowledge of the day. There seems to be not a vestige of truth in this gossip. He lived to an advanced age, variously estimated as 85, 90, 104, and even 109 years, and died in Thessaly.

At the risk of boresome repetition I wish to give another quotation (from Adams):

It will readily occur to our reader, then, that our author flourished at one of the most remarkable epochs in the intellectual development of the human race. He had for his contemporaries Pericles, the famous statesman; the poets Æschylus, Sophocles, Euripedes, Aristophanes, and Pindar; the philosopher Socrates, with his distinguished disciples, Plato and Xenophon; the venerable father of history, Herodotus, and his young rival Thucydides; the unrivalled statuary Phidias with his illustrious pupils, and many other distinguished names, which have conferred immortal honor on the age in which they lived and exalted the dignity of human nature. Nor was Greece the only region of the earth remarkable at this time for moral and intellectual improvement; for, if we may believe Oriental chronology, Confucius and Zoroaster had gone off the stage of life only a very few years before the dawn of this celebrated age of Grecian superiority in the arts and sciences.

The ancients assumed the existence of four elements—water, fire, air, and earth. All things were necessarily combinations of these elements. The four cardinal conditions of the body were: dryness, warmth, coldness, and moisture. Variations of these states, proceeding from one to another, determined health or disease. Corresponding to the four elements they had four cardinal fluids, yellow bile, blood, mucus, and black bile. All disease processes were simple, in three steps: crudity, coction, and crisis; or degeneration, preparation, and evacuation. The fluids degenerated, were collected, and prepared for evacuation, which, occurring, terminated the disease by crisis. If any of these steps were not completed or failed, particularly the crisis, there would be an incurable disease, secondary affection, etc. The crises occurred on odd days. The art of the physician consisted in choosing the right time to interfere in all conditions. Nature, however, was the healer and the physician only her servant. Beside these proximate causes, Hippocrates speaks of remote causes rather emphatically; injudicious mode of life, climatic and meteorological influences, seasons, endemic and epidemic constitution, place of residence, etc.

It is interesting to note the frequency and obviousness of the remnants of this pathology now, in lay medicine at least. A diagnosis of biliousness is a favorite, and the liver is a very popular seat of trouble. Recently I saw a case in consultation, of that mental condition we know as melancholia. Upon physical examination the patient showed marked signs and symptoms of an inflamed gall bladder. Remembering the philology of melancholia (Greek for black bile), I cannot but admire the acuity of observation by the ancients of subjective symptoms in connection with physical disease. In reading any medical text or paper of the present day, it is remarkable that an even day is scarcely ever mentioned, an incubation period is five or seven days, never four or six, and so on ad infinitum.

We have come to pay little attention to the more simple methods of treatment. Our system of dietetics has resolved itself into a smug statement of calories and percentages with rather limited application. In "Regimen in Acute Diseases," our author discusses his views of dietetics in minute detail. Barley decoction or "ptisan" as the ancients knew it, was considered a very valuable adjunct in the treatment of any disease and its survival for all this time certainly indicates some value. We have no cereal water, bland and not astringent, that will take the place of barley water in our infant feeding. Hippocrates and his associates considered fever a combination of heat and dryness, to be treated with coolness and moisture, hence barley decoction. The only argument was as to whether the barley itself should be strained out or not. The sum of his advice seems to be not to change food suddenly. If treatment is started with strained ptisan, continue and do not change, and the same in regard to full and slender diets. At present the starvation treatment of typhoid fever holds the record with a mortality of only seven per cent., but you well know the dire results of a sudden increase of food in such a treatment. The Bellevue Hospital typhoid diet with the enormous quantity of five thousand calories per day does almost as well and convalescence is said to be extremely rapid, however, the generous diet must be started in the very

beginning and there must be no cessation or all is lost. The argument is that, the stomach and intestines, if kept stimulated by food, will furnish secretion and digest in proportion to the food taken; but if no food is furnished, they lose a part of the power of digestion. In speaking of starvation diets our author speaks of outsiders coming in and feeding the patient followed by prompt recovery. The meddlesome neighbors have always been present and to our great chagrin a great many times it seems.

The use of water, fomentation, and wines is discussed in a general way in "Regimen." Hippocrates states that warm fomentations promote the formation of pus and warns against their use in various conditions. He also advises the use of aromatics with purges to protect the stomach; still another piece of advice applicable to modern practice. The course of pneumonia is accurately described in this work and the manner of death in such a case. The ancients used water, as water alone and as "hydromel," a mixture of honey and water. In Galen's commentaries on Hippocrates' use of water in the treatment of fevers, we find the distinguished Roman stating that he could cure a case of fever with nothing but water, used in proper amount, at the proper time and in the proper manner. Hydromel was accredited with various virtues, but it was certainly laxative. The close of "Regimen" is concerned with baths and bathing; in bathing invalids extreme care and gentleness is urged, both bath and patient should have the proper preparation; one should not bathe immediately after eating, etc.—in brief, rules for the bath that we ourselves observe and have or think we have, scientific explanation.

A diagnosis is reached by consideration of the history, symptoms, and physical signs in the great majority of our cases. The clinical laboratory we use in necessity. The diagnoses at Cos were reached in the same manner. Allow me to present a case history in the words of our author, from the first book of Epidemics.

> Philiscus, who lived by the wall, took to bed on the first day of acute fever; he sweated; towards night was uneasy. On the second day all the symptoms were exacerbated; late in the evening he had a proper stool from a small clyster; the night quiet. On the third day, early in the morning and until noon, he appeared to be free from fever; towards evening, acute fever, with sweating, thirst, tongue parched; passed black urine; night uncomfortable, no sleep; he was delirious cn all subjects. On the fourth all the symptoms exacerbated, urine black, night more comfortable, urine of a better color. On the fifth, about midday, had a slight trickling of pure blood from the nose; urine varied in character, having floating in it round bodies, resembling semen, and scattered, but which did not fall to the bottom; a suppository having been applied some scanty flatulent matters were passed; night uncomfortable, little sleep, talking incoherently; extremities altogether cold, and could not be warmed; urine black; slept a little towards day; loss of speech, cold sweats; extremities livid; about the middle of the sixth day he died. The respiration throughout, like that of a person recollecting himself, was rare and large, and the spleen was swelled upon in a round tumor, the sweats cold throughout the paroxysms on the even days.

It will be readily seen that diagnosis was not so much the object as prognosis. Galen, in his commentaries, says of this case, that the fatal outcome was apparent as early as the third day when the relapse occurred. Be that as it may, it certainly is a graphic description of a severe fever with regular exacerbations on the even days, and antedates Cheyne-Stokes classic respiration by several centuries.

Before leaving the first book of Epidemics we shall quote one more paragraph as an introduction to our consideration of the "Prognostics."

> The physician must be able to tell the antecedents, know the present, and foretell the future—must meditate these things and have two special objects in view with regard to disease, namely, to do good or to do no harm. The art consists in three things—the disease, the patient, and the physician. The physician is the servant of nature, and the patient must combat the disease along with the physician.

The ancients set great store on prognostic ability, particularly the students at Cos. For a great many years they collected statistics and embodied the results in what is known as the "Coan Prognostics." In compiling his work known as "Prognostics," Hippocrates doubtless drew a great deal of his material from this collection. However, the work of our author is unique in lucidity of expression and acuity of observation. Disease of the entire body and surgical affections, part by part, are taken up in this, one of the largest works. The views are too numerous to consider in any detail, but the reader will be surprised to find so much information in such an ancient text. The first paragraph is very expressive and worthy of our notice:

> It appears to me a most excellent thing for the physician to cultivate prognosis, for by foreseeing and foretelling, in the presence of the sick, the present, the past, and the future, and explaining the omissions which patients have been guilty of, he will be the more readily believed to be acquainted with the circumstances of the sick, so that men will have confidence to entrust themselves to such a physician. And he will manage the cure best who has foreseen what is to happen from the present state of matters. For it is impossible to make all the sick well; this, indeed, would have been better than to be able to foretell what is to happen; but since men die, some even before calling the physician, from the violence of the disease, and some die immediately after calling him, having lived, perhaps, only one day or a little longer, and before the physician could bring his art to counteract the disease; it therfore becomes necessary to know the nature of such affections, how far they are above the powers of the constitution; and, moreover, if there be anything divine in the disease, and to learn a foreknowledge of this also. Thus a man will be the more esteemed to be a good physician, for he will be the better able to treat those aright who can be saved, from having long anticipated everything; and by seeing and announcing beforehand those who will live and those who will die, he will thus escape censure.

The statement giving credence to the divine nature of disease in this paragraph is the only such admission in all the works of our author. All the commentators are puzzled by this, since Hippocrates was the first and only physician of that time to refuse the theory of the divine origin of any disease. In the treatise on the "Sacred Disease" we find the following: "It is thus with the disease called 'sacred'; it appears to me to be no more divine nor more sacred than other diseases, but has a natural cause from which it originates like other affections. Men regard its nature and cause as divine from ignorance and wonder," and a great deal more in like strain. Certainly Hippocrates did not believe in the divine origin of disease. In copying and rewriting ancient manuscripts, the com-

mentators and copyists many times introduced their own views as interpolations. We plead ignorance concerning original manuscripts, but such would seem a reasonable explanation to us.

An extract from the "Prognostics" is probably the best known contribution of our author to medicine, which is always attributed to its source and correctly. We remember well "a sharp nose, hollow eyes, collapsed temples; the ears cold, contracted and their lobes turned out; the skin about the forehead being rough, distended, and parched; the color of the whole face being green, black, livid, or lead colored." This passage we have appropriated and condensed into two words, "Hippocratic facies," and as such it appears in every modern medical text. Adams calls attention to the description of death, very much like that quoted, as given by Celsus, Lucretius, and Shakespeare. The death of Falstaff as described in the second act of Henry the Fifth is very suggestive of Hippocrates. "For after I saw him fumble with the sheets, and play with flowers, and smile upon his fingers' ends, I knew there was but one way: for his nose was as sharp as a pin, and he babbled of green fields. So he bade me lay more clothes on his feet: I put my hand into the bed and felt them, and they were as cold as any stone."

The treatment of disease at so remote a period was naturally very simple. Of the two schools advocating, on the one side, mild and expectant therapy, and on the other more active and vigorous treatment, Hippocrates placed his reliance more with the first and used for the greater part measures of dietetics and regimen. Hydrotherapy was extensively used in its various forms. Venesection was very popular with the ancients, but our author advised it only in the rarest cases. In the appendix to "Regimen" he describes the symptoms of apoplexy accurately and advises venesection in selected cases just as we do to-day in the same type of case.

Almost all the modern forms of medicament were used, mention being made of cerates, ointments, clysters, emulsions, gargles, fomentations, and suppositories. Prescriptions containing a very great many different drugs are given. Some of these are: galbanum, cumin, artemisia, scammony, bryonia, seseli, hellebore, madder, pepper, asafetida, carrot, linseed, myrrh, pine fruit, euphorbia, squills, anise, cantharides, mandragora, charcoal, crocus, and copper sulphate, besides ptisan and hydromel as mentioned before. The treatment of pneumonia is described in detail. A prescription for empyema is given as, "Cut some bulbs of squill, boil in water and when well boiled throw this away, and, having poured in more water, boil until it appears to the touch soft and well boiled; then triturate finely and mix roasted cumin and white sesames, and young almonds pounded in honey, form into an electuary and give." Empyema meant to Hippocrates any disease in which pus came from the lungs or chest. Who among us has not used squills or hydrocyanic acid dilute? A prescription for opening the bowels, "Pour upon figs the juice of spurge, in the proportion of seven to one: then put into a new vessel and lay past when properly mixed. Give before food." "Syrup of figs" was discovered twenty-five hundreds years ago!

The consideration of the surgical methods of treatment of Hippocrates is the hardest blow of all to our pride of modern achievement. The generalities of procedure are preserved in the work on "The Surgery," along with many particulars. Special works are devoted to injuries of the head, fractures, articulations, ulcers, fistulæ, and hemorrhoids. He was a bold and fearless operator in those cases which he believed should be operated upon, probably too bold in trephining, according to our present belief. He described the anatomy of the cranium in an excellent manner for that time and for long centuries afterward, the first corrections being those of Fallopius in the sixteenth century. Injuries of the head are classified as, (1) Simple fractures, (2) contused fractures, (3) fractures with depression, (4) fracture of outer table alone, and (5) fracture distant from point of impact, and prescribes treatment for each class. In order to detect a suspected fracture he cleansed the bone and applied a dressing of ink; upon curetting the surface, the fracture would be clearly indicated by a black line and if the line could not be scraped away he trephined. The dressings were drying in character and warning was given of the danger of putting a dressing on over the hair. The peculiarities of the child's cranium were known and commented upon, and also the fact that paralysis occurred on the opposite side of the body from the injury. Directions for trephining are clearly given—drill and then inspect with a probe so that the brain will not be injured. The trephine of that time varied in form. They used a straight rod shape like a screw driver, one turned by means of a bow, and even had one with an offset crank like the brace of today.

Practically the whole of three large books is devoted to fractures and dislocations; many rare and unusual varieties being described. Adams ascribes this remarkable knowledge of fractures and dislocations to the numerous accidents of the games and to the wide travels of the physicians. The proper function of a dressing was recognized, namely, to hold the parts in apposition and immovable. Those feats which were beyond human strength in the reduction of fractures, were performed by many mechanical devices. The dangers of tight bandages, and of splints over bony prominences, were mentioned and the serious results described nicely. Volkmann's paralysis might well have had another name. By smearing a cerate on the skin and then on each layer of the bandage as it went on, a stiff dressing, very much like our plaster bandage, was secured, and in some respects I should think very superior to it. Broken legs are directed to be placed in extension and the use of canal or gutter splints is described. A broken arm is directed to be reduced by traction and manipulation, splinted and bandaged, and placed in a flexed position with the hand midway between supination and pronation. Sounds familiar, doesn't it? Club foot was recognized as a false dislocation and treated by splints and bandages in infancy. Compound fractures of all parts are described and treatment is given. They are to be reduced at once, when possible, either manually or by means of an iron lever placed between the ends of the bones; failure to reduce means the immediate amputation of the projecting bone.

The treatment of ulcers is noteworthy on account

of the pharmacological list given—alum, sodium carbonate, copper, ox-gall, pomegranate, saffron, oak decoction, vinegar, wine bark of the fig, lead, zinc oxide, silver, elaterium, verdigris, wool fat, and sulphur; all of them, practically, astringents and antiseptics or dessicants. Purging for inflamed sores was advised. The curettment of the edge of indolent ulcers was practiced but it was also known that an ulcer would not heal if surrounded by inflammation or a varix. When applying a cataplasm, care not to cover the sore, but only the parts around, is to be observed, so that the pus may have free egress. Burns were treated by astringent and emolient applications. Full directions for the operation of venesection are given, but its use is rarely advised. When used, however, it was to be pushed to the limit of safety.

Fistulæ were, by choice, treated by incision as at present, but treatment by introducing a pack or tent saturated with caustic of some variety is also described. The practice of passing a seton and incising by gradually drawing it tighter, was known and highly recommended in suitable cases. Extreme cleanliness was to be observed no matter what method of treatment was to be pursued. Hemorrhoids were cured by actual cautery, caustic applications and even excision. A very elaborate description of a rectal speculum is given in the book on "Hemorrhoids," and directions for applying caustic on a holder, through this are given. Astringent suppositories of gall, myrrh, alum, etc., were used as palliatives. The following description of an operation for hemorrhoids gives a pretty vivid picture of the surgery of the time: "When the cautery is applied the patient's head and hands should be held so that he may not stir, but he himself should cry out, for this will make the rectum project the more."

We have nothing in modern medical literature or teaching which corresponds to the "Aphorisms" of Hippocrates. The title of the work indicates its nature and content. Medicine has become so much less empirical and has grown to such an extent that any attempt to present modern medicine in the form of aphorisms would be very futile. However, the permanent value of these ancient statements is recognized and they are often quoted, too many times without a knowledge or appreciation of their source. We are reminded very often that "Experience is fallacious and judgment difficult." With all our advance we have made no better statement of fact than this, "Phthisis most commonly occurs between the ages of eighteen and thirty-five years," and "Diarrhea attacking a person afflicted with phthisis is a mortal symptom." And there are many others.

Medical ethics is a problem today and evidently was among our ancient brethren. Their solution of the problem seems applicable now, for who, observing the oath of Hippocrates in letter and spirit, could be criticized? The "Oath" and the "Law" are so well known and appreciated that any words of mine would most certainly be useless, for, "It would be vain to blame and useless to praise."

I have endeavored to direct your attention to the history of the age of Hippocrates, his theories of pathology, diagnosis, prognosis, dietetics, treatment, both medical and surgical, and his idea of ethics. If I have aroused any interest in medical history, which I feel to be too much neglected, or in the practice of the greatest physician the world has ever known, I am well satisfied. The study of the works of Hippocrates has been a source of much pleasure, and I must confess that to me it has been of very practical value. One more quotation from Francis Adams: "I need scarcely say that, as a medical author the name Hippocrates stands preeminently illustrious. In this way he has left monuments of his genius more durable than the marble statues of Phidias, his contemporary, and as enduring as the tragedies of Sophocles, or the Olympic odes of Pindar."

LATENT TUBERCULOSIS.*

By O. W. McMICHAEL, B.A., M.D.,

CHICAGO, ILL.

THE call to arms revealed to us our national strength and weakness. We believed ourselves strong—but who could have believed us as strong and virile as the battlefields of France proved us? Who, on the other hand, could have believed that one-third of the young men of our nation would have been found unfit to fight, and that one in every hundred was a blighted victim of tuberculous disease?

We knew we had a tuberculosis problem and we knew that we would have to provide for the blinded, the battle-maimed, and for those who would fall out in the march because of some defect in their physical machinery. Plans were made for the reconstruction necessitated by the ravages of war. In the minds of most, reconstruction meant the establishment of factories for artificial limbs, but no one dreamed that the greatest tax upon our resources and the greater number to be cared for would be, not the victims of shot and shell, but those who were struck down from within by the arch enemy of the human race, the tubercle bacillus. We knew that the enemy was lying in wait and never in the history of warfare was such a well-planned effort made to exclude from the ranks men who presented evidence of the disease. Confidence was felt that the medical knowledge of the country would exclude from our army every man who carried the seeds of death. Our complacency was short lived for in the very first lists from France of those who gave their lives for their country, was the cause of death shot or shell? No. Tuberculosis. Day by day these reports came in till some one grew ashamed, so ashamed in fact that the word was changed to "died of disease."

Some one had blundered, for in spite of all the difficulties that surrounded the detection of this hidden enemy, he does not strike without warning, and for a man to be sent to France and die of tuberculosis before he reached the battle lines stands to the everlasting discredit of the medical man who passed him as physically fit. Apologists might find excuse in the haste of war but those of sterner mould can only feel toward him as

*Read at twentieth annual session of the Ohio Valley Medical Association at Evansville, Indiana, on November 11 and 12, 1919.

they do toward the man who sends to the front a defective shell. What sort of excuse are we to find from him of whom it was said that "The President of the United States of America to all who shall see these presents, greeting; know ye that reposing special trust and confidence in the patriotism, fidelity, and abilities of ——— I do hereby appoint him a member of local board ——" and who sends to camp for enrollment in the United States Army men so far advanced with tuberculosis that they find their last earthly resting place in the hospital ward of their first camp. It would seem at first thought that these must be isolated cases and due to the ignorance of only a few, but when we think again that the overwhelming problem in reconstruction is the adequate provision for that class of man which many times over outnumbers all the others—the victims of tuberculosis, we must realize that the fault lies in our conception of the disease and our methods of its detection. What is wrong with us? Where does the fault lie? Is it lack of skill?—it can't be that, for the American medical man is better trained, of higher grade of intelligence, and is more resourceful than the medical man of any other country on earth. We used to think the German was all wise in medicine and all powerful in battle, but the Yankee soldier would not believe and broke the German line on the fields of France. The Yankee doctor believed when the German told him that if a man did not have rales in his chest he could fight—and there we met defeat. Now are we caring for a long line of men who were sent across the seas with latent tuberculosis.

The lesson was a bitter one and from our defeat we can learn that the stethoscope is not the only aid to diagnosis and that we can and will by more modern methods learn to recognize early tuberculosis.

Modern medicine is a tower of Babel and because of the confusion of tongues we fail to understand each other. To one tuberculosis means that the victim is soon to close his eyes, to another it means only a trivial ailment that a couple of weeks in the country, a few dozen eggs, and a few quarts of milk, and all will be well. How hard it is to keep our thinking caps on straight. How hard it is to get rid of the old word "tubercular," a relic of the days before the discovery of the tubercle bacillus, meaning "like tuberculosis," and substitute the more exact term "tuberculous" which means infected by the tubercle bacillus.

The terms "incipient," "moderately advanced," and "advanced" mean different things to different men. To illustrate this, how often do we read a paper on "incipient tuberculosis" and find included symptoms and signs which can be produced only by advanced destructive processes in the lung! So it is with "active tuberculosis." When we are asked, "Has he active tuberculosis," we must know what concept the questioner has of "active." Has he in mind the warfare between the body cells and the tubercle bacillus or has he in mind the battle at a particular place in the line where the enemy is making a drive and threatening to break through?

Words were invented to conceal thoughts and phrases to lead them astray. The phrase "look for the initial lesion" has misled us in our understanding of tuberculosis and if you turn it upside down you will find it stamped "Made in Germany."

American investigators have proven that the tubercle bacillus may penetrate the tissues without leaving a trace at the point of entrance, scatter to various parts of the body, and there multiply. Instead of an initial focus or primary lesion we may have a thousand foci no one of them large enough to interfere mechanically with the function of the organ in which they are lodged.

It must be remembered that the tubercle bacillus is not a motile organism. The only way in which we can account for its presence in the tissues of the body is that it was carried there by the leucocytes along the only line of travel, the blood and lymph streams. Given the presence of the tubercle bacillus in the tissue, what happens? Every cell which obtains its nourishment from another cell must produce a substance which will digest that other cell so that it may employ the elements of the other cell for its own upbuilding. These digestive elements we call toxins because they are poisonous or destructive agents. Another law of nature is that every toxin-producing cell produces these harmful substances far in excess of its own needs. Therefore if we are to seek for early evidence of the presence of the tubercle bacillus our search must be directed, not to the damage that results only after years of growth of the colonies of germs so extensive that they interfere seriously with the functions of the organs in which they have established their habitat, but to the more subtle effects of the slow poisoning of the host by the excess of the tuberculotoxins.

We are constantly warned that we must differentiate between tuberculous infection and tuberculous disease. Does this mean that the individual who has a tuberculous infection is not entitled to our consideration till a certain degree of damage has been done? It is true that dame Nature is a better doctor than we are and prevents the vast majority of the cases of tuberculous infection from becoming tuberculous disease, but that does not relieve us from our duty as good scouts of seeking out the enemy without waiting till he shows his head. If when he keeps his head out of sight we could assume that he was asleep, we might be justified in saying he was latent.

Latent tuberculosis is a term as indefinite as incipient tuberculosis and one hesitates to employ it lest it convey the impression that there is a period when the tubercle bacillus is inactive. The only time a tubercle bacillus is inactive is when he is dead. Even then he is a trouble maker for the concentrated lipoids of dead disintegrated tubercle bacilli play a part in the destruction of lung tissue and cavity formation. The term latent tuberculosis then may be applied to the period between infection and the development of sufficient damage to enable us to recognize tuberculous disease. Throughout this period the human body is waging warfare against the toxins produced by the tubercle bacillus. Toxins are poured out into the circulation, anti-

toxins are produced, and so the battle goes. The host is well or ill or only slightly disturbed as the tide ebbs and flows.

The function of every organ in the body may be disturbed at times and to catalog the symptoms which may be produced by latent tuberculosis we ought to include the entire list of symptoms of functional disturbance.

Since it is the fad now to teach that all tuberculous infection is contracted in childhood and that practically all children are infected, wouldn't you think that all children should be studied for evidence of latent tuberculosis? and yet when a child who is "run down" or poorly developed is brought to us we grab a stethoscope, listen and hear nothing, look at his tongue, take out his tonsils, and let it go at that. We do not see the drooping lower eyelids, the bluish pink triangle under his eyes, the dilated veins on his chest, the small beady cervical glands; we do not see that the upper part of his chest is not developing as it should, that the lower part of his chest is broader than it should be; we do not learn that he is wearing the same size clothes that he did last year. Of course he hasn't tuberculosis because he has no rales in his chest, but a tuberculin test would tell a different story.

The tired school girl is brought to us because she cannot keep up with her work. She is tired all the time. She has not lost weight, she always was thin, just like her father who always was thin and who, by the way, is carrying around in his chest an old tuberculous cavity that no one knows about, though they do say that he was threatened with lung trouble when he was a young man. She has no cough, so we do not look at her chest. We do notice that her thyroid is a little larger but many girls at puberty have enlarged thyroids. She is just "run down" so we prescribe a tonic, whatever that is, she picks up again, and in two or three years she is sent to a sanatorium. We do not see that that enlarged thyroid meant a response to a cry for help. We did not know that the blood was burdened with an excess of tubercle toxins, that the suprarenal glands were unable to meet the burden of controlling elimination and telegraphed the pituitary body, which in turn whipped up the thyroid. Disturbance of endocrine balance is a result of toxemia. Tubercle toxemia is constantly present in varying degree in latent tuberculosis. Lowered blood pressure is a constant sign of tubercle toxemia.

In the absence of definite signs how are we to recognize latent tuberculosis? The answer is tuberculin. Immediately the objection is raised that many who have no tuberculosis react to tuberculin. Granted, but none react to tuberculin who have no tuberculous infection. Let us establish first who are and who are not infected and then latent tuberculosis will take on a new meaning, and many thought to be latent cases will be found to be actively tuberculous.

The tuberculous soldier has taught us that latent tuberculosis may easily become active tuberculosis and that we must give more earnest consideration to the manifestations of infection and toxemia.

25 East Washington Street.

ULCER OF THE ESOPHAGUS FROM THE STANDPOINT OF AN ESOPHAGOSCOPIST;

ITS CAUSE, SYMPTOMATOLOGY, DIAGNOSIS AND TREATMENT.*

By JOSEPH EASTMAN SHEEHAN, M.D.

NEW YORK.

I AM very happy to address this Society to-night on this topic, because I want to emphasize the fact that it is amazing how little this rather common lesion is referred to in the literature or in textbooks; also, to emphasize the more general use of the esophagoscope and the string test of Einhorn as an aid in diagnosis, and the employment of the duodenal feeding tube of Einhorn in the treatment of esophageal ulcer.

By esophagoscopy is understood the examination of the esophagus with the aid of lighted tubes introduced through the mouth.

The esophagus begins at the lower edge of the cricoid cartilage, opposite the lower border of the sixth cervical vertebra and ends at the cardiac opening of the stomach, opposite the fifth thoracic vertebra. It is about 25 cm. (10 inches) long and begins 15 cm. (6 inches) distant from the teeth. The average diameter of its lumen is 2 cm., which at the upper and lower constriction is reduced to 1.5 cm.

The lumen of the esophagus is narrowed at four points, namely: (1) at the cricopharynx, (2) where it crosses the left bronchus, (3) where it crosses the aorta, (4) near the end as it passes through the diaphragm, the cardio-hiatus.

Historical.—Kussmaul, in 1868 and later on Mikulicz, were the first to take up the subject of esophagoscopy. In 1895, Kierstein developed an esophagoscope; Killian, my teacher, the father of bronchoesophagoscopy, in 1896 perfected the procedure of esophagoscopy. Credit should also be given to Brunning of Germany, Gusiez of France, and Jackson of America for our present knowledge of esophagoscopy.

Location.—The most frequent site of esophageal ulcer is at the fourth constriction, that is between the cardia and the hiatus. Seventy-five per cent. of all esophageal ulcers occur in this location. The cricopharynx is the next most frequent location for ulceration and finally it is found in the constrictions where the left bronchus and aorta cross the esophagus. It is my experience ulcers of the fourth constriction of the esophagus are more frequent in males than in females.

The ulcers may be circular, as occurs in the syphilitic, semicircular, round, or irregular. In this latter class the ulcer may extend up and down the tube for a considerable length. Several may be clustered together, or ulcerations may occur at both ends of the esophagus.

The favorable site of esophageal ulcer when it occurs at the fourth constriction is on the right posterolateral wall.

Etiology.—It is quite impossible in a considerable number of cases to determine the cause of esophageal ulcerations. Regurgitation of gastric juice or islands of gastric mucosa aberrant in the mucosa seem to underly this condition. (Davis.)

*Read before the Harlem Medical Society, Wednesday evening, November 5, 1919.

(*a*) This condition is favored by stenosis of the pylorus or duodenum or by an hour-glass stomach. (Davis.)

(*b*) Hurried eating with the intake of quantities of hot or cold food over a long period of time may be a potent cause.

(*c*) Syphilis.

(*d*) Tuberculosis.

(*e*) Malignancy.

(*f*) A scratch or erosion of the mucous membrane caused by swallowing foreign bodies, particularly those with a sharpened edge, as a fish-bone or chicken-bone, or pieces of metal, such as a pin, may and generally does give rise to an ulceration.

(*g*) Injuries of the esophagus, as in suicidal intent.

(*h*) The ingestion of corrosive fluids, as carbolic acid, iodine, or concentrated lye.

Symtomatology.—Superficial ulceration of the esophagus causes few if any symptoms. It is only, as a rule, in the long-standing, deep-seated ulcerations that definite symptoms are produced; that is in ulcerations which have penetrated to the muscular coat or through it. Dysphagia is present in a goodly proportion of cases, and this dysphagia is one of the main diagnostic points in the differentiation of ulcer of the stomach.

Immediate pain on swallowing and tenderness over the sternum are characteristic symptoms of esophageal ulcerations. These symptoms are more or less constantly present when the ulcer is at the fourth constriction.

Sometimes and quite often one elicits pain upon pressure over the region of the lower border of the spleen. Because of the pain and dysphagia, in some cases, patients take little food with the result of a mild or severe type of inanition. There may be only a dull burning pain or a sense of pressure. Hematemesis may occur. A tickling or choking sensation and a collection of mucus in the mouth may be the only symptoms. Some patients may be nauseated and vomit.

Diagnosis.—In all cases of suspected ulcer of the esophagus, no matter how remotely referable are the symptoms, esophagoscopy, preceded by the string test of Einhorn, should be employed. 65 per cent. of the 27 cases in my series of esophageal ulceration, which were proven by the esophagoscope, gave a positive string test.

In many cases it is only after routine broncho-esophagoscopy, that an ulcer of the esophagus is detected. The *x*-ray adds nothing; I rarely resort to it as a means of diagnosis in this condition.

In the esophagoscope and the string test of Einhorn we have two of the most useful methods at our command, as an aid in diagnosing esophageal ulcerations. I make a plea for their more general use.

Treatment.—After the diagnosis of the ulcer is made and its exact location is determined, I prepare the patient for an esophagoscopy. The ulcer is generally located with the aid of the esophagoscope under cocaine or ether anesthesia. I then apply a 20 per cent. silver nitrate solution over the whole surface of the ulcer or ulcers. The Einhorn duodenal tube is inserted and feedings are started as soon as the bucket enters the duodenum. The patient generally remains in bed for one week after which he is allowed to get up and about for a week or ten days. The tube is then withdrawn from the interior.

Large doses of bismuth subnitrate, combined with argyrol crystals and magnesium ustum, are given three or four times daily. This is the only substance which is taken by mouth. It acts as a coating to the ulceration. 500 c.c. of a physiological saline solution is given per rectum in the form of a Murphy drip twice daily. After the tube is removed the string test is employed to note the progress of healing. Many times after this treatment one gets a negative string test, showing that the ulcer has healed.

Conclusion.—The purpose of this paper is to urge upon the profession the more general use of the esophagoscope and the string test of Einhorn in diagnosing ulcerations of the esophagus, and the general employment of the duodenal tube of Einhorn in the treatment of this condition.

24 East Forty-eighth Street.

Medicolegal Notes.

Privileged Communications.—The Arkansas Supreme Court holds that in an action originating in a municipal court one who there said she had no objection to a physician testifying did not thereby waive her right to object to testimony of the physician on trial of the case in the circuit court, where it was shown she did not understand that she had a right to keep him from testifying.—Metropolitan Life Ins. Co. (Ark.), 209 S. W. 77.

Due Care and Skill in Setting Fracture.—In an action for alleged negligence in resetting a broken leg so that the ends of the bone overlapped it was held that in the absence of a showing that such a condition would have been at least improbable had the leg received reasonably prudent and ordinarily skillful surgical treatment, it could not be said that the mere pathological condition of the leg in and of itself sufficed to show negligence on the part of the defendant. "The difficulties and uncertainties in the practice of medicine and surgery are such that no practitioner can be required to guarantee results, and all the law demands is that he bring and apply to the case in hand that degree of skill, care, knowledge, and attention ordinarily possessed and exercised by practitioners of the medical profession under like circumstances."—Zoterell v. Repp., 187 Mich. 330, 153 N. W. 695. With respect to the failure to attain a complete bony union, the plaintiff's experts themselves testified that there was no way for an average or even a skilled surgeon to tell whether ligamentous or bony tissue was being deposited between and around the fractured ends of a broken bone in the process of reuniting, without opening the wound. While one expert testified that it was good surgery to open the wound and staple the bone, especially where, as here, there was an oblique fracture, none of the experts gave it as their opinion that it was not good practice to rely altogether upon casts and splints, as the defendant did. It appeared that a plaster of Paris cast was put on the leg on April 9, 1912; that another cast was put on on April 12, and possibly another on April 17; that the cast was removed on April 25, and that a yucca splint was then put on and held in place by a light bandage. The patient wanting to go to his ranch, the defendant told him he could go by being careful and using his crutch all the time, keeping the splint on for about two weeks. No further treatment was given. There was no testimony that anything covered by this treatment was improper. It was held that the evidence failed to show any lack of care and skill on the part of the defendant in setting and treating the fractured bone, and judgment for the plaintiff was reversed.—Perkins v. Trueblood, California Supreme Court, 181 Pac. 642.

PHYSICAL THERAPY IN MILITARY AND CIVIL PRACTICE.

BEFORE the war physical therapy was coming into its own, because it is one of the most effective methods for preventing disease and because all signs seem to point to the fact that medical practice of the future will be very much more of a preventive nature than it has been in the past. The war brought out into strong relief not only the extreme value of physical therapy as a means of training men into hard condition, rendering them better able to undergo the vicissitudes of strenuous warfare and to resist disease, but it also demonstrated in the clearest manner possible that as a remedial and curative agent it was highly efficacious. The war may be said to have placed physical therapy on a sound foundation, for the lessons that the war taught with regard to the usefulness of physical therapy may be employed with success in civil medical practice. In an interesting paper on this subject, read at the annual meeting of the Association of Military Surgeons, last October, by Commander William Seaman Bainbridge, M.C., U.S.N.R.F., and published in the *Military Surgeon* for December, 1919, it is pointed out that the lesson learned by the bitter experience of war will have been more or less in vain unless its principles are applied to civil life. In order that the necessary and laudable object should be achieved with the least friction possible, Bainbridge brings forward three suggestions.

The first of these is that civilian hospitals in time of peace shall have departments fully equipped for the employment of physical therapy, so that they can be utilized, not only for the treatment of the injured, but also as far as may be possible to secure a maximum of physical efficiency among the general population. Attention is drawn to the fact that the war has demonstrated most conclusively that no patient recovering from a serious wound should be discharged until every effort has been made to send him out in as sound a condition as circumstances permit, and with reasonable assurance that no remediable disabling after-effects persist. It has been the custom to send the patient out as soon as he is able to be removed. According to Bainbridge, it appears reasonable to argue that many a stiff joint or other disabling after-effect of operation or injury might have been completely remedied or avoided by retaining the patient for a longer time on the in or out patient's list. Physical agents, such as thermal, mechanical, and electrical treatment, curative workshop treatment, and so on, might have been intelligently utilized. The fallacy also of prolonged immobilization of a joint injury or fractured limb is considered and the success of Dr. Charles Willems in treating joint lesions by a method which is based upon the principle of immediate active mobilization of the joint is cited in support of the view. It will be remembered by our readers that Dr. Willems gave an exhaustive account of his mode of treatment in the "Medical and Surgical Lessons of the War Series" in the MEDICAL RECORD of June 7 and 14, 1919, xcv, 23 and 24. Bainbridge holds that it is obvious that every large civil hospital equipped to provide all kinds of physical therapeutic treatment is a potential base hospital, convalescent camp, or institution for the reduction of disabled soldiers, while at the same time it is actively engaged in doing its part toward maintaining the highest standard of physical efficiency so far as the civilian population is concerned. The latter point is manifestly very important.

The second suggestion is that civilian hospitals shall be so equipped in time of peace as to be more quickly available by the Government in an efficient condition for military service in the event of war. That is to say that in time of peace there should be more hospital beds, ready for war emergency than in the past. The third suggestion is that military hospitals, both temporary and permanent, should be equipped in such a manner during peace that when utilized in time of war the maximum of medical and surgical efficiency may be attained.

The equipment for employing physical therapy skilfully and scientifically must be personal as well as mechanical. The best mechanical equipment will be useless unless there is a sufficient number of skilled exponents of this form of treatment. Bainbridge recommends that lay workers be trained in the various methods in which physical therapy is applied. He further thinks that it is conceivable that military hospitals equipped with facilities for making use of physiotherapy might be utilized as training schools for men to be called upon later to administer the various physical adjuvant measures which have been found so essential in the war now over.

Of course the benefits of physical methods in securing and maintaining general health are too obvious to require emphasis. Dr. Bainbridge has made out a very strong case for physical therapy in his paper and his suggestions may be commended to the earnest attention of the medical profession throughout the country. As Major Corbusier said in the discussion on this paper,

there is no doubt we are far behind European countries in our use of physiotherapy, and it is incumbent upon us to introduce the principles, which our army surgeons learned by experience in the war, into our civil hospitals. He also insisted upon the necessity of every medical school being equipped with means for teaching and training in all forms of physical therapy.

ENCEPHALITIS LETHARGICA IN ENGLAND.

In 1918 and 1919 a disease occurred in England and Wales which puzzled medical men considerably. It presented features resembling poliomyelitis and cerebrospinal meningitis, and yet differed from these infections in certain other respects. According to numerous papers which appeared in the English medical press, the distinctive symptoms of the obscure malady seemed to be those of an acute general disease associated with a condition of increasing languor, apathy and drowsiness, passing into lethargy; progressive muscular weakness passing into complete disablement; and a combination of various cranial nerve palsies, of which ptosis, squint, and nystagmus were characteristic signs. So languorous and lethargic are those afflicted with this disease that the complaint is usually termed in the lay press "sleeping sickness." The matter was made the subject of inquiry by some of the prominent medical men of the English Local Government Board and the result of these inquiries formed the subject of a special report.* From the evidence adduced the general conclusions arrived at were that the illness under consideration was not a form of acute poliomyelitis, as had been assumed by many, and that its prevalence in epidemic form depended on conditions other than those necessary for the epidemic prevalence of that disease. It was decided that the disease was encephalitis lethargica, and in order to obtain early and complete information of all cases of the disease in different parts of the country, it was made compulsorily notifiable for a period of one year. It is stated in the medical supplement to the Forty-Eighth Annual Report of the English Local Government Board, 1918-1919, that further evidence is required before a conclusion can be arrived at as to whether the disease is infectious in the sense that a person suffering from an attack can convey the infection to other persons. The investigation proved that the disease was not botulism or food poisoning, as was suggested by some, but it seems to have ignored its coincidence with its pandemic of influenza, not only the present one but that of 1889-90.

From the clinical point of view three types are distinguished: (1) With general disturbance of the functions of the central nervous system, but without localization; (2) with various localizations; (3) mild or abortive. The incubation period is said to be of variable duration. The prodromal period includes the first seven days, but may extend to two or three weeks, with lethargic somnolence, headache, diplopia, general lassitude, and occasionally vomiting and diarrhea. The acute symptoms include a febrile temperature, marked asthenia, stupor, difficulties in speech, and spasmodic twitchings of the face. In the type with localizations of the central nervous system, paralysis of accommodation with diplopia is very frequent and early. There may be ophthalmoplegia, external or internal, with ptosis. The muscles innervated by the facial nerve may also be paralyzed and likewise those of the tongue and pharynx, rarely those of the limbs. Sensory troubles are the exception. Death appears due to paralysis of the respiratory nervous centers. An explanation was offered in the report for the widespread sporadic distribution of encephalitis lethargica. It was suggested that the malady belongs to that group of affections, including cerebrospinal fever and acute poliomyelitis, in which the pathological agent is more frequently present in the human organism than the clinical symptoms indicate. Either as the result of the breakdown of the immunity to the effects of the virus which the individual who harbors it has up to that time enjoyed, or as the result of a nonimmune person becoming infected with a strain of the virus which has attained a degree of pathogenicity described as "specific," a manifestation of the disease occurs. In interepidemic periods or when cases are less frequent, such cases only appear to be sporadic. All these diseases—acute poliomyelitis, cerebrospinal meningitis, and encephalitis lethargica—are obscure in many features, the report says, but the latter disease on account of its comparative novelty or because its differential diagnosis has been made only recently is the most obscure. A warning is given in the annual report that it is already apparent that the biological properties of encephalitis lethargica are altering, as the successive examples of multiple cases indicate. It may be only a short stage in the evolutionary progress of the causal organism for its activities to be manifested in wider epidemic form.

It is curious that the report does not consider the relation of encephalitis lethargica to pandemic influenza, or at least does not note the coincidence of the two affections. Lethargic symptoms were so common during the visitation of influenza in 1772, that the epidemic was characterized as one of "sleeping sickness." The disease prevailed in 1889-90, appearing in Eastern Europe when the first part of the epidemic was subsiding and traveling westward, precisely as it did during the present influenza epidemic. This of course does not prove that encephalitis lethargica is a cerebral localization of influenza, but the coincidence is sufficiently striking to warrant a more careful study than it appears yet to have received.

*Report to the English Local Government Board, New Series No. 21, upon an obscure disease, Encephalitis Lethargica.

VITAMINES.

THE recent report on vitamines prepared by a joint committee of the Lister Institute and of the Medical Research Committee of London, issued at the end of 1919, illustrates the rapid growth of knowledge concerning the processes of life. Hardly more than a decade ago, it was believed that Liebig's work and that of his successors had placed the chemistry of food on a sound basis. The living cell required food to repair waste, to provide for growth, and to supply energy. The constituents of a suitable dietary were proteins, fats, carbohydrates, and inorganic matter which forms the ash when the bodies of animals or plants are burned. The usual mixed diet of man and animal contains these substances in large amounts. But it contains them in varying proportions, and associated with many other substances. Experiments were made by different workers to prepare artificial dietaries containing only the necessary ingredients in the purest forms in which they could be obtained. Some ten years ago it began to be apparent that a really "pure" diet was insufficient. Rats and mice fed on it assumed a miserable appearance after about a month, and rapidly perished. Minute traces of certain materials, such as extract of yeast, added to the diet, prevented the development of the untoward consequences. Some addition, minute in quantity, had to be made to the recognized raw materials for growth and the vehicles of energy. Knowledge from this source was then correlated with knowledge derived from the study of certain morbid processes.

It had long been known empirically that scurvy attacked seafaring men fed on preserved foodstuffs, but that the disease could be cured by fresh vegetables or the juice of oranges and lemons. The Eastern scourge known as beriberi was traced to a substitution of rice decorticated by the machinery of the West for rice prepared in native fashion, and it became manifest that a constituent of absolute necessity to health had been removed with the husk. Hence the conception of vitamines or accessory foodstuffs came into being. They are required in quantities so minute that they cannot be regarded as sources of energy, while their presence or absence does not affect the number of calories in the diet. They are organic bodies, developed in green leaves in the presence of the solar rays, or in the embryo during its germinal period in the seed. Herbivorous animals obtain them from plants and carnivorous animals from their prey. Three have so far been recognized a fat soluble body, the absence of which gives rise to rickets in young animals; a water soluble body, necessary to the growth of young animals and warding off beriberi; and lastly, an antiscorbutic substance. The report discusses the distribution of these bodies and the means of securing their presence in food. Fortunately there is no reason for alarm if a varied diet containing fresh vegetables and fruits, milk and butter is available. But where the diet consists chiefly of long cooked and preserved foods there is very serious danger, especially in the case of young subjects.

THE PROGNOSIS OF COMPLETE ARRHYTHMIA.

IT is most probable that there is no necessary relationship between complete arrhythmia and cardiac insufficiency, because a pronounced insufficiency may arise although the cardiac rhythm remains regular, and on the other hand, in subjects leading an active life, the heart adapts itself to a completely irregular rhythm, to such an extent that the latter constitutes about the only pathological phenomenon in these individuals. It is none the less true that the menace and degree of cardiac insufficiency dominate the prognosis of complete arrhythmia, and depend essentially upon the different factors of the reserve strength of the myocardium. The factor whose importance is the most immediate is evidently the functional condition of the myocardium, itself depending on its anatomical condition. But there are also other factors which exhaust the reserve strength of the heart by causing an exaggeration of its work.

Among these factors the mode of life must be taken into consideration; certain subjects can tolerate their arrhythmia only by following a very strict hygiene and an activity in proportion to the resources of the myocardium. The occurrence of intercurrent complications, among which a fresh rheumatismal attack is the most important, is to be feared, because they may weaken the patient's general health or produce lesions of the various viscera, particularly the heart; likewise pleuropulmonary and renal affections, the reaction of which on the heart is immediate. The concomitance of complete arrhythmia and a valvular lesion acts deplorably by the circulatory hydraulic disturbance it causes or exaggerates. It is manifest that complete arrhythmia is accompanied by a maximum of cardiac insufficiency in cases with valvular lesions, among which the predominating part of mitral lesions is explained by the very fact of their frequency. Finally, consideration should be given to the frequency and gravity of the successive paroxysms of cardiac insufficiency, each of them being accompanied or followed by visceral lesions which are increased with each attack and consequently aggravate the degree of myocardial failure.

As a factor of strength-saving of the myocardium, the beneficial action of general dietetics is to be considered, and especially the stimulating action of cardiac tonic medication comes into play, and their opportune use must act as a counterweight to the causes of cardiac failure. It is the favorable realization of these various eventualities which permits the coexistence of an extreme perturbation of the cardiac rhythm with a satis-

factory general and functional state of health. Nevertheless, the heart of a patient suffering from complete arrhythmia is in a very precarious state of functional equilibrium which can be destroyed by some very trifling cause. The prognosis would, however, be relatively favorable in the subjects who had adapted themselves to their arrhythmia, were it not for the constant menace of sudden death from an outburst of ventricular fibrillation, although fortunately this is rare.

The Indications of the Cesarean Operation.

A very good critical review has been recently offered by Couinaud (Thèse de Paris, 1919), on the indications of cesarean section in cases other than contracted pelvis and neoplasms. The operation is rarely indicated in congenitally narrowed vagina because during gestation the vaginal walls become soft and yielding so that spontaneous delivery can take place. But in cases of cicatricial atresia gestation has no effect on the condition, and since it is difficult to estimate the degree of adhesion between the vaginal walls, bladder, and rectum the cesarean operation is indicated. Imminent rupture of the uterus is naturally a formal indication for the operation, while primary rigidity of the cervix is likewise an indication if the stenosis is very marked, but usually labor will progress. Should it not do so dilatation of the cervix should not be resorted to, nor vaginal cesarean section, the only rational treatment being the classical operation. In cases of secondary rigidity of the cervix—which in reality is an infectious edema of the cervix—hysterectomy may be indicated, but the cesarean operation is to be rejected, and this also applies to eclampsia. When the fetus is excessively large the indications for cesarean section are deduced from the state of maternal shock, the condition of the fetus, the menace of uterine rupture, as well as the relative indications based upon the estimate of the difference between the size of the fetus and the pelvic diameters in previous labors. If the fetus is manifestly suffering and dilatation is incomplete, the head not engaged, and the child is at term and viable, the operation should be done at the express wish of the mother for a living offspring. This same applies to face, shoulder, and forehead presentations. Cesarean section is not indicated in low insertion of the placenta unless there is complex dystocia at the same time, but generally the classical treatment will be satisfactory. In cases of retroplacental hemorrhage the operation should be done if rupture of the membranes is fruitless and if the hemorrhage is so serious that the various methods of artificial dilatation of the cervix will be too slow for controlling the situation. When there is an irreducible procidentia of the cord cesarean section may be undertaken, but the fact must not be lost sight of that a dead child may be extracted or one whose vitality is seriously compromised. Unquestionably, the indications for this life-saving operation should be greatly increased, but at the same time it would seem that the relative indications for its execution must be looked upon as rather exceptional in practice. In spite of the technical progress made during the past decade in this operation, it will nevertheless remain a major interference, and should it be indiscriminately resorted to—as is unquestionably the case in some quarters—the future of this otherwise excellent operation will certainly be compromised.

Vaccinotherapy in Acute Staphylococcic Osteomyelitis.

Vaccinotherapy has been recently essayed in acute staphylococcic osteomyelitis of adolescence. From the technical viewpoint stock vaccine is first employed when the case comes under observation, but later on an autovaccine is used in some cases. The injection can be made at almost any point and the first doses should never exceed a tenth of a cubic centimeter, which represents two hundred million bacteria. Afterwards the dose may be doubled but the next injection must not be given until the phenomena of reaction caused by the preceding injection have disappeared. To obtain a cure, from two to seven injections have been necessary, according to the case. The reactions met with have been mild ordinarily, while local reactional phenomena seem to be exceptional. The general phenomena consist in a slight thermic rise and a marked acceleration of the pulse rate, lasting for one or two days, while a very minute amount of albumin may appear in the urine. Vaccinotherapy appears to be contraindicated, or at least it will be without avail, when the patient presents the peculiar typhoid state common in the severe infectious processes. In fact, this treatment is to be recommended only in those instances in which the local symptoms are more important than the general phenomena. The first favorable sign observed after vaccination is the improvement of the general condition—a drop in the temperature, the return of both appetite and sleep. Then the local symptoms retrogress, the spontaneous pain first disappears, then the pain on pressure, likewise the inflammatory phenomena. A fluctuating collection can be detected by palpation and this may persist or become absorbed. Frequently no hyperostosis or sequestra develop after vaccinotherapy so that a favorable evolution takes place with remarkable rapidity. It is not uncommon for the temperature to become normal within a week or ten days, and the child may use the involved limb in from a fortnight to four weeks.

Simple Venereal Ulcer.

An elaborate study of this subject from the literature, contributed by Rabut in the *Gazette des Hôpitaux* for December 20, 1919, xcii, 80, shows how little our knowledge of soft chancre has advanced in recent years. Under the head of mediate contagion we find mention of transmission by soiled apparatus such as scissors, but in the absence of details do not know whether the scissors were actually contaminated or merely caused a traumatic port of entry for the virus. The incidence varies greatly and is markedly increased by any cause which brings together thousands of people, as great expositions and especially the late war. After relaxation of police control of prostitution chancroid also increases. Old experiments in animal inoculation have been repeated and it is significant that

the monkey is believed to be the only animal to be successfully inoculated with chancroidal virus, the free border of the eyelid being the optimum locality. However, some old accounts of positive results in rabbits and cats seem authentic. Inoculable pus is sterilized by a heat of 45° C. Left untreated a chancroid heals in time but requires two and even three months if untreated. In a case of phagedenic chancroid the process had lasted three years. The author does not allude to two important subjects. One is the confusion of granuloma venereum of the tropics with phagedenic chancroid, some reported cases of the latter clearly belonging under the former head. The other is the discovery during the war of Ducrey's bacillus carriers in the persons of prostitutes themselves free from chancroid who harbored the germ in the vulval secretions.

Twenty-five Years of Antidiphtheritic Serotherapy.

It was before the Rome Congress in 1894 that Roux presented the case for antitoxin so thoroughly that it was at once accepted by authorities throughout the world. Twenty-five years later Martin summed up our experience with the remedy to date (*La Presse Médicale*, October 18, 1919, xxvii, 60) before a session of the Paris Academy of Medicine. Before the serum era the mortality from the disease varied from 50 to 100 per 100,000 inhabitants. Since that period the figure has been less than 20, and often less than 10. The hospital mortality throughout the world now runs from 10 to 15 per cent. of those stricken. During the five years of warfare the number of soldiers attacked by the disease was about 30,000 in all the hospitals, and the total number of deaths about 600, or 2 per cent. Before the use of antitoxin Paris lost from 14 to 45 inhabitants weekly from the disease. She now loses, and has for many years, from 2 or 3 to 13 a week; or in other words the former minimum has become the maximum. Indeed for the past ten years the maximum has not exceeded 7 weekly. Naturally during the twenty-five years the population has increased notably, no account being taken of this fact in the statistics. No one to-day can doubt that diphtheria antitoxin has made good. The enormous number of repeated serum injections of all kinds made during the war has brought home the fact that the dangers of anaphylaxis have been grossly exaggerated. Again the hypertoxic case once regarded as doomed in advance is now known to be curable by intensive treatment, including intramuscular and intravenous exhibition. The latter can be carried out without fear of anaphylaxis if the serum is diluted ninefold and thrown in the vein very slowly.

News of the Week.

Cripples Find Employment.—The employment bureau of the Institute for Crippled and Disabled Men, in the two years of its operation, has placed 1,800 cripples in well paid positions, according to a recent report. Of this number 84 were right arm amputations, 81 left arm amputations, 217 with one arm partially disabled, 84 with both legs amputated or both legs paralyzed, 340 with one leg amputated, 100 with right or left side paralyzed, 85 with spinal injuries, 14 with locomotor ataxia, 775 lame, and the rest with a variety of handicaps.

Shortage of Visiting Nurses.—In the report of the year's work of the Henry Street Settlement, New York City, attention is called to shortage of visiting nurses and the need of increasing the nursing service. During 1919, 35,433 patients in the Boroughs of Manhattan, Bronx and Richmond were cared for by the nurses of this Settlement. The nurses made 261,690 visits to patients under the care of the various centers, 10,000 of which were of a health advisory and social service type, and 1,320 were visits among factories where employees' welfare and health work is under the supervision of the Settlement. The nursing centers provided 11,655 office dressings during the year, and 1,299 visits were made of cases referred to the Settlement by the Red Cross.

Town Meeting Starts Influenza Epidemic.—The snowbound hill town of Cummington, Mass., had its annual town meeting on February 2. A week later 163 of its 700 inhabitants were ill with influenza. Energetic measures of relief were instituted by the Hampshire County Red Cross Chapter, and a relief expedition to the town was headed by the Reverend G. A. Wightman, county missionary. The shortage of food and medicine was relieved, and efforts made to secure nurses. The two resident doctors were reported to be exhausted from their labors.

Osler Memorial Meeting.—Owing to a misunderstanding of a telephone message the date of the Osler Memorial Meeting, announced in the issue of February 14, was incorrectly given as February 21. The meeting will be held on February 28 at 8:30 p. m. in the New York Academy of Medicine. The speakers will be Drs. Francis J. Shepherd of Montreal, Thomas McCrae of Philadelphia, Edward C. Streeter of Boston, and William H. Welch of Baltimore.

State Aid for Tuberculosis Patients.—The New York legislature has been asked to appropriate one million dollars for State aid for tuberculosis patients to enable them to receive care in the country, in boarding houses licensed for the purpose, where medical supervision and proper sanitary conditions will be assured, and where the patients can have plenty of air and sunlight. A similar bill was defeated last year. Health Commissioner Copeland of New York City is said to approve the measure.

Typhoid Epidemic in Galicia.—It is reported that typhoid fever in epidemic form is raging in Southeastern Galicia, 100,000 deaths having occurred since the epidemic started. One out of every five taken ill dies, and several villages have been left without a single survivor. At Stanislau, according to the report, the hospitals are so crowded that typhoid victims are lying in the streets, people not afflicted being afraid to go near them, and the doctors being too busy to give them attention. American Red Cross officials have been asked by the Polish Government to rush doctors to the stricken district.

Sir James A. Grant, Canadian physician and statesman, died at Ottawa on February 6, at the

age of 89. Death resulted from a broken hip, caused by a fall. He was the sole survivor fo the First Canadian Federal Parliament. His "How to Live 100 Years" and other contributions attracted attention in this country and abroad.

Captain Oscar C. Frundt, M. C., U. S. Army, of Jersey City, has been awarded the Distinguished Service Cross for extraordinary heroism in action while commanding a hospital train in Eastern Siberia in June, 1919. Captain Frundt was graduated from Cornell University Medical Department in 1911.

Charitable Bequests.—By the will of the late Sophie Jacobs Gerstle, widow of R. H. Gerstle, the following institutions among others, will receive $500 each: Mt. Sinai Hospital; Montefiore Home, and United Hebrew Charities. Beth Israel Hospital and the Washington Heights Hospital will receive each $250.

Obituary Notes.—Dr. PHILIP G. SANDERSON of Detroit, Mich., died of pneumonia on January 28, after an illness of three days. He was 52 years of age. He was graduated from the Illinois University College of Medicine in 1899.

Dr. A. F. DURHAM of Sparta, Ga., died of cardiac disease January 30. He was graduated from Jefferson Medical College, Philadelphia, in 1887.

Dr. JOHN M. GRANT of St. Louis, Mo., died of pneumonia on January 29, at the age of 56. He was graduated from the Missouri Medical College in 1889, and specialized in surgery. He was a member of the American Medical Association.

Dr. MAY CUSHMAN RICE of Chicago died from influenza-pneumonia February 4, at the age of 57. She was graduated from Northwestern University Woman's Medical School in 1896 and specialized in Rœntgenology. Dr. Rice was a member of the American Medical Association and other organizations, and was the author of "Electricity in Gynecology."

Dr. JOHN JASPER SEWALL of Newport, Me., died February 4, at the age of 63. He was graduated from New York University Medical College in 1884.

Dr. SALLY ROBINSON CREIGHTON BEST of New York City, died February 6. She was graduated from Cornell University Medical College in 1894. During the war Dr. Best served the United States Government in the censorship of drugs. She was an active member of the Executive Committee of the American Women's Hospital.

Dr. GEORGE H. BALLARAY of Paterson, N. J., died February 10, at the age of 72. He was graduated from the College of Physicians and Surgeons, New York City, in 1869. He had been a member of the staffs of the Paterson General Hospital, St. Joseph's Hospital, Paterson, and was surgeon to the Woman's Hospital, Newark. He was a member of the American Medical Association, the Medical Society of the State of New York, the New York Academy of Medicine, and various other organizations.

Dr. FRANK W. MERRITT of Jay, Me., died January 25, after an illness of two years, at the age of 64. He was graduated from the Medical Department of the University of Vermont in 1889.

Dr. JOSEPH TALBOT MACLEAN of New York City died January 28. He was graduated from Bellevue Hospital Medical College in 1876.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 6, 1920.

Annual Meeting of the British National Dental Association.—The annual meeting of the National Dental Association opened at the Connaught Rooms, London, on Jan. 27. Delegates representative of 11,000 members or thereabouts attended the meeting. The discussion turned largely on the future of the unregistered dental practitioners under the new legislation. At present there are two opposing camps in the British dental world, the registered and the unregistered dentists. The registered number 5,000, while the unregistered count up to about 15,000. Mr. Victor Lawson, in his address as president, referred to the prospect of the members obtaining their charter from Parliament. They were working, he said, for recognition and status. They were men who understood dentistry, the majority of them having been apprenticed for upward of five years, and they were capable of carrying on surgeries of their own. They entirely objected to vulgar and blatant advertising and canvassing, and conducted ethical and conservative practices. No qualified man could say more. It had been suggested that much harm had been done by unregistered dentists, but he denied strongly that this was so. In view of the large number of unregistered dentists, cases of malpractice were few and far between. It was undisputed that the ethical and capable unregistered practitioner was both useful and necessary in rendering beneficial service to the general public, and could not be done without. The president claimed high authority for the statement that it was the intention to take on and register en bloc members of the Association and of the Incorporated Dental Society, Ltd. The meeting passed a resolution protesting against the absence, eleven months after the date of the report of the departmental committee on dentistry, of legislation to eliminate automatically the advertising and canvassing dental quacks. It was decided to make strong recommendations to the Ministry of Health, in the interests not only of both sections of the dental profession, but of the public health, calling for an immediate measure which would adequately protect the public from these gross evils. The resolution was carried. At the annual dinner of the Association, which was held on the evening of Jan. 27, Mr. F. A. Seddon, M.P., said that the object of the Association was that those who were described as "unregistered" should be permitted to render, in future, as in the past, a great service to the community without any stigma attaching to them. Had there been no unregistered dentists, tens of thousands of people in Great Britain would have received no attention at all. The limited number of practitioners on the register precluded them from meeting all the wants of the community. When, in the early days of the war, many thousands of willing fighters were rejected owing to defective teeth, the unregistered men came forward and did work which could not have been accomplished had it been left to the registered

side of the profession. If for no other reason than that they were now entitled to receive recognition. He hoped that what was now the moral right of the unregistered would soon become a legal right. Mr. Seddon further expressed the conviction that dental treatment would soon become as obligatory for children in the elementary schools as learning to read and write.

The war has not only taught and emphasized the vital need of properly caring for the teeth of a nation, and especially of its children, but has shown plainly that, in order that dental work may be really effective, it must be done by skilled men. The dental profession should take a high position and that this may come to pass, the whole body of dentists must be raised to a higher standard, and advertising dentists and quacks must be got rid of. The only way to do so is to bring in legislation requiring a dentist to give proof of his knowledge by examinations, written, oral, and clinical, before he can be registered, and making it a penal offense for an unregistered dentist to practise his profession. Those who are practising at the present time no doubt will be allowed to register, but none will be allowed to advertise vulgarly. Such legislation will be unjust to none and will be for the good of the public health.

Appointments to Chairs of Medical Science.—The Daniell Chair of Chemistry at King's College, vacated by the appointment of Dr. A. W. Crossley to the Directorship of Research to the British Cotton Industry Research Association, has been filled recently by Dr. Samuel Smiles. Dr. Smiles was educated at the University College, London, and at the Universities of Paris and Jena. He has had teaching experience at University College, London, and since last year has been Professor of Organic Chemistry at Armstrong College, Newcastle. There has been of late an increasing tendency on the part of hospital medical schools to entrust the appointment of medical professors to the Senate of the University of London. This is quite a new departure, as in the past the medical schools have shown a decided, jealous determination to keep such appointments in their own hands, but they seem to have learned by experience that they get better men by making use of the Senate. Dr. H. E. Roaf has just been appointed by the Senate to the University Chair of Physiology at London Hospital Medical School, and Dr. T. S. Vincent has been appointed to the University Chair of Physiology at the Middlesex Hospital Medical School. It may be said that more instances of the same tendency are pending. Dr. Roaf, since 1911, has been lecturer on physiology at St. Mary's Hospital Medical School, and for three years during the war was in charge of the Pathological Laboratories at Cairo. Dr. Vincent was from 1904 Professor of Physiology and Biochemistry in the University of Manitoba. That the advantage to be gained from solidarity with the University should be thus recognized by the hospitals is of great importance and interest, especially when the fact is taken into consideration that it is being subjected to considerable criticism from other quarters. Mr. S. B. Joel and Mr. J. B. Joel, nephews of the late Barney Barnato, the well-known South African millionaire, have given the sum of £20,000 for the endowment of a University Chair of Physics at the Middlesex Hospital Medical School. The munificent gift is interesting and instructive for more than one reason. It shows, it is to be hoped, that the rich men of Great Britain are awakening to the need of the medical schools and hospitals for money sufficient to conduct medical research on a wide scale. Another reason why the endowment is important is because it makes a novel, albeit national, experiment. Physics and scientific medical research should go hand in hand, and particularly so far as radium, *x*-ray, or electrical treatment is concerned, because physics is the fundamental part of such treatment. Medical students require a knowledge of physics so as to be able to understand the why and wherefore of radium, *x*-ray treatment, and so on. The institution of a chair of physics at a medical school is wise and in the proper order of things and doubtless other hospitals in London and elsewhere would welcome a like endowment.

Hospital Saturday Fund.—This year's grants to hospitals and kindred institutions from the Hospital Saturday Fund amount to £54,305. The total is £4,727 more than last year's awards, and is the largest sum ever distributed. As many as 233 institutions will benefit from the distribution, among which are 40 general hospitals, which will receive £19,961. At these 40 hospitals during 1918 there were available 9,427 beds, of which the number in daily occupation was 7,913. The weekly cost per bed ranged from £1, 5s, 4d to £3, 17s, 6d, giving an average of £2, 15s. The total number of patients using these beds was 102,964, and the period of occupation varied from twelve to forty-five days. In the out-patient department no fewer than 825,241 patients were treated, the number of attendances being 3,320,671, and the cost of treatment fluctuated between one shilling and sixpence and eight shillings and fivepence for each patient.

Persons Who Live Longest.—Dr. Otto May, medical officer of the Prudential Assurance Company, in a lecture on "Turberculosis in Relation to Life Assurance," delivered at the Royal Institute of Public Health, on Jan. 29, 1920, said that the ideal type for longevity was the rather short man, especially if in later years he was somewhat under weight. Life assurance officers looked with suspicion upon young entries who were tall and much under weight, especially if they had any history connecting them with tuberculosis. People who were above the average weight were not looked upon as good risks at any age. Underweight in the early years of life was a handicap, but over weight was looked upon as a worse handicap. It was the thin, wiry chap who was likely to be profitable to the insurance officer. An investigation carried out in America had shown that tall, underweight men showed considerably higher mortality than short, thin men.

Tuberculosis and the Industrial Classes.—At a meeting of the Divisional Committees and Secretaries of the National Union for Insurance, held recently in the Pinsbury Town Hall, London, Dr. Noel D. Bardswell, principal tuberculosis officer to the London Insurance Committee, spoke on "Some Aspects of the Tuberculosis Problem, Viewed from the Standpoint of the Industrial Classes." He said that of all diseases tuberculosis

was the most inimical by far to the life and capacities of the worker—of all the claims which were made upon insurance societies, that from tuberculous persons was much the heaviest. Every year no fewer than sixty thousand people died from the disease in England and for those who died there were probably ten to twenty times this number who were suffering from it. The main predisposing causes of the disease were lack of fresh air, of proper food, of sunlight, the presence of dirt, drink, insanitary houses, workshops, and workplaces of all kinds. If these things were attended to people would have a better chance of warding off infection; and food, particularly milk, should be carefully inspected to guard against the conveyance of the disease to otherwise healthy persons.

Some Questions of Heredity.—Dr. W. Bateson, lecturing on biology at King's College on Jan. 26, 1920, mentioned that night blindness had been traced through eight generations, not skipping one. Other afflictions, including deformities, were sometimes carried on from generation to generation under curious circumstances, while the prospect of feeble-minded parents having children who were not similarly afflicted was practically nil. So far as color blindness was concerned, the results obtained were important. A man might have no progeny so afflicted, but there had been no case reported of a color-blind woman having a son with normal sight. Dr. Bateson said that he was often questioned on the subject of intermarriage—say with a cousin. He knew of no practical deduction which he was entitled to draw, but he would rather marry his cousin if he knew her family than marry someone else's cousin about whom he knew nothing.

Obituary. — A very distinct, in many ways a unique, figure passed from human ken when Charles Louis Taylor died on December 21, at the age of 70. Taylor had been assistant editor of the *British Medical Journal* for twenty years, and a member of the staff for close on thirty-one years. He was a Scotchman, born in Peterhead, Aberdeenshire, and possessed most of the Scotchman's best and most typical characteristics. Throughout his life he was a diligent student and acquisitive in a high degree of all knowledge bearing upon the medical profession and especially, perhaps, that which was concerned with the historical and literary side. His education well qualified him for the post of assistant editor of a leading medical journal. The early years of his life were lived in France, where his mother took him when an infant on the premature death of his father. The first part of his education was given in Aberdeenshire, where he was thoroughly grounded in the classics, and then was placed in the Scots College, Balladobid, Spain, remaining there for four or five years. At Balladobid he became steeped in ancient literature and learned to speak and write Latin with the facility of one accustomed to use that language as the medium for conversation. The next few years he spent mostly in France and about the age of 20 he entered the medical school of University College, London, where he passed through the curriculum. It will thus be gathered that he was peculiarly well equipped for medical, literary, or journalistic work. Before joining the staff of the *British Medical Journal* in 1886, he was secretary to Sir Morell Mackenzie, the nose and throat specialist. As assistant editor he was a great success, for not only was he possessed of medical and wide literary knowledge, but he had a colloquial command of French, Spanish, and Latin, a working knowledge of Greek, Italian and Portuguese, and a more than ordinary acquaintance with German. In addition, Taylor was one of those men who believed that anything worth doing at all was worth doing well; he had that faculty designated by Carlyle as genius, an infinite capacity for taking pains. He fulfilled the often monotonous duties and drudgery of his post with the greatest care. Although the greater part of his writing was done for the *British Medical Journal*, he did a certain amount of literary work in other directions. It may be mentioned that he was responsible for the series of articles which appeared in the *Journal* under the title, "Nova et Vetera"—and wrote most of these excellent essays dealing largely with the history of medicine. Taylor was immensely popular with his colleagues and esteemed for his geniality, loyalty, and kindness. Sir Clifford Allbutt's appreciation of the deceased editor, which appeared in the *British Medical Journal* of January 17, 1920, is given by one who knew him intimately as a man and a writer and supplies a vivid presentation of both. Sir Clifford says: "Taylor was a delightful writer, erudite in many ways, general and particular, but especially in historical subjects. He took pleasure in some byways of scientific history, on which and other such matters he contributed much to the contents, and not a little to the gaiety of the *Journal*. Taylor's wit and keen sense of humor were always entertaining, often brilliant and effective. Many of his paragraphs, fugitive, alas! were in their ironical and humorous vein singularly happy. Moreover, his wit was always barbed with point and precision. No inaccuracy escaped him and he would smilingly pin the error to the counter or dismiss it with a whimsical allusion. Sometimes he permitted himself to draw a sharper arrow, when folly and presumption had to snarl; but he was too kindhearted to use the weapon unless the gravity of the occasion required it." Like many able and brilliant men of the essentially student temperament, Taylor was of a retiring disposition and seemed to prefer the companionship of his family and a few chosen friends to the plaudits of the public. Whatever fame he gained came to him unsought. He is survived by his widow, two daughters, and his son, Dr. C. J. G. Taylor, of Nuneaton, Warwickshire, who served throughout the war as surgeon in the navy.

A CONSTITUTIONAL QUESTION.

To the Editor of the Medical Record:

Sir:—An important matter which is to come before the meeting of the Medical Society of the State of New York in April, is the question of the constitutionality of the election of a delegate to a general office in the society during the period of the term for which he shall have been elected a delegate. This matter came up before the House of

Delegates during the election of a candidate for president at the last meeting of the society, the discussion being based upon Art. III, Sec. 3, of the Constitution of the State Society, which is as follows: "No delegate elected to the House of Delegates shall be a candidate for a general office in the Society until after the expiration of the term for which he shall have been elected a delegate."

In the specific case concerning which discussion arose, it was held by some that the office of delegate and the term for which he was elected terminated the minute he resigned and his resignation was accepted by the body that elected him a delegate. Whether or not an interpretation of the constitution can be adjudicated by vote during an election contest, the fact remains that many members hold with the minority on this occasion that this interpretation is not in accordance with the meaning of Article III, Sec. 3, of the Constitution, and they hold that this provision covers the term for which the delegate was elected, irrespective of whether he resigned or not before that term expired. Under the Constitution of the State of New York a member of the Legislature is not allowed to accept an appointive office during the continuance of the term for which he shall have been elected a legislator. The House of Delegates is the legislative body of the State Society and the delegates are its legislators. In this as in some other respects the Constitution of the State Society seems to have been modeled on the principles of the Constitution of the State of New York.

3. Some Incidents in the Life and Military Campaigns of Baron Larrey (1766-1842). William Pearce Coues.
4. The Technique of Citrated Blood Transfusion. Henry C. Marble.

1. The Surgical Treatment of Peptic Ulcer.—P. E. Truesdale states that when medical treatment and rest have been tried for weeks or months and the symptoms fail to yield to such measures or return after short periods of relief, the problem of dealing with the disease falls into the category of surgery. The surgical treatment consists first of all in a careful review of the clinical and laboratory record of the case. After considering this evidence the first step in the operation is to establish the diagnosis by direct examination of the stomach and duodenum through an abdominal incision. This is not always an easy thing to do because other changes often exist at the pylorus which may be mistaken for ulcer. The most common of these is a thickening at the pyloric ring from hypertrophy of the pyloric sphincter muscle or the adjacent musculature of the pylorus. To a mind that fully expects to find ulcer, a thickened muscle at the pylorus is quite liable to be satisfactory evidence that ulcer does exist in the thickened tissue although no scar is visible. Pericholecystitis with adhesion of the gall bladder to the pylorus or duodenum, with thickening and induration of the gut, may be mistaken for ulcer. Whenever one is in doubt over some indefinite tissue change, it is more judicious not to interfere. Whenever ulcer is present the signs are definite, not indefinite. In view of the tendency of the ulcer to perforate and bleed, gastroenterostomy is now supplemented by excision of the ulcer when it is accessible. Ulcer of the stomach is excised by the knife or cautery in every case. The cautery may be used for obliteration of peptic ulcer wherever located, but it is indicated in a group of cases where the ulcer is high on the lesser curvature. As a supplementary operation to excision, gastroenterostomy is sometimes done and sometimes not, depending upon the patency of the pylorus and the amount of deformity produced in the excision of the ulcer itself. Whenever the ulcer is in the pyloric end of the stomach, and the condition of the patient permits, pylorectomy is the operation of choice. Under adverse circumstances it is more prudent to do the operation in two stages. The writer has performed pylorectomy for ulcer in twenty-seven cases with but one death, which occurred from leakage of the duodenal stump. He now guards against this accident by the use of infolding linear sutures in two layers over the duodenal end; upon this is sutured a portion of the omentum. In general it may be said that operation for chronic ulcer cannot be applied by rule of thumb, and it is evident that the slowly shifting technique shows the ideal operation not vested in any procedure which leaves the ulcer. The most satisfactory method of attack aims at excision of the ulcer in a way which does not "alter the complex relations of the alimentary functions and the more complex forces which maintain these functions." Such a procedure takes into consideration the important fact that the alimentary tract is a one-way passage.

7. The Coordination of the Principles of Chemistry with the Laws of Immunity in the Treatment of Tuberculosis. Benjamin S. Paschall.
8. Futility of Intraligamentary Shortening of the Round Ligaments When Operating for Other Intrapelvic Conditions. Sigmund Goldberg.

1. Wassermann Contradictions Considered from the Clinical Point of View.—Abr. L. Wolbarst holds that the Wassermann test and the gonorrhea fixation test should be made by at least three serologists working independently, that the serum should be taken simultaneously and sent to the different laboratories under identical conditions, and that one serologist is not to be depended on, however capable he may be. From the observations detailed, the writer finds that three serologists will agree in approximately fifty-three per cent. of Wassermann tests and approximately forty-two per cent. of gonorrhea fixation tests. In other words, the chances are about fifty-three in a hundred that three serologists will agree on any given serum. Curiously enough, they are more likely to agree in the negative cases than in the positive cases. This study emphasizes the point that more attention should be devoted to the clinical features of the cases, not trusting so implicitly on the laboratory workers for diagnosis.

6. Compulsory Health Insurance.—Charles Howard Chetwood. (See MEDICAL RECORD, February 14, 1920, page 290.)

8. Shortening of Round Ligaments When Operating for Other Intrapelvic Conditions.—Sigmund Goldberg, challenging the correctness of the textbook description of the round ligaments as guy ropes or stays for the uterus, holds that by the various methods of fixation of the uterus the object sought, namely, the complete cure of the patient, is not attained. The uterus, thus fixed, has been relieved of one pathological position, and, by the art of surgery, fastened into another. Normally the uterus, poised in the true pelvis, is constantly in a state of movement of greater or less degree, and yet maintaining under all conditions a certain area of movability. Fixation by intraligamentary shortening of the round ligaments is contrary to na-

ture. In retropositions of the uterus the round ligaments are not overstretched, as in some other conditions, and, never having been overstretched, they have not lost that peculiar tonicity of plain muscle and they require no shortening or fastening for the purpose of holding the uterus when replaced. In view of this, the writer holds that it is reasonable to assume that the uterus, being released from its enforced restraint in abnormal position by the necessary operative procedures upon the concomitant pathological conditions, will rise by virtue of the inherent tonicity of the round ligaments and other normal factors, and will so remain without being fastened by any of the modern operations into another abnormal position with added dangers of intestinal strangulation, adhesions to the incision, etc. Acting upon this assumption, in twenty cases he deliberately left the uterus unsupported by any procedure, and found in these cases that the uterus would maintain a normal poise notwithstanding the Trendelenburg position. Not only that, but he found and demonstrated that when he attempted to retrovert the uterus he found that, due to the resiliency of the nonstriated muscular tissue of the round ligaments, the uterus would immediatley spring into place. In all these twenty cases the patients have been examined from one to several months subsequent to operation, and in every instance the uterus has been found in normal position and normally movable. From this experience and from the recorded experience of other observers, the writer draws the following conclusions: (1) That in retropositions of the uterus the round ligaments are never overstretched, and therefore require no shortening. (2) By virtue of the normal resiliency of the nonstriated muscular tissue of the round ligaments, when the uterus is released from its retroincarceration, it will maintain its normal position. (3) That all intraabdominal operations for the purpose of fastening the uterus when released only put it into another abnormal position and therefore oppose those natural forces which are always active.

8. A Case of Syphilis of the Anterior Horns. George M. Goodwin.

3. The Significance of Some General Biological Principles in Public Health Problems.—Raymond Pearl holds that the great outstanding problems of public health are really broad biological problems, which can never be satisfactorily solved until they are looked at on this basis, nor until ascertained general biological principles have due consideration in their study. In particular, it must be recognized that heredity imposes a hard and fast limitation on the effectiveness of palliative or control measures in public health. What is particularly needed, as an essential and integral part of the science of the etiology of disease and of public health doctrine, is a basis collection of organized and digested facts regarding the inheritance of the diatheses of various important diseases, notably phthisis, the pneumonias, and heart and kidney affections. Such a body of knowledge can be acquired only by the slow, laborious, painstaking accumulation, by specially trained field workers, of data regarding family histories, and the searching analysis of such records by biologists and clinicians thoroughly trained in quantitative methods of research. Investigations of this sort are being actively prosecuted in the writer's department of the School of Hygiene and Public Health of Johns Hopkins University, with the support of a grant made for the purpose by the National Tuberculosis Association, and it is hoped that means will be found shortly for extending this type of work to other diseases.

7. The Surgical Treatment of Gummatous Osteitis of the Skull.—A. W. Adson bases his views on his observation of several cases of gummatous osteitis of the skull in which the necessary surgical measures were employed, namely, draining the suppuration, removing the sequestrum or dead bone, and stimulating granulation and epidermization over the denuded areas. If the fluctuating area is opened, a sequestrum and pus are usually found, surrounded by roughened edges of bone. In the older lesions these fluctuating masses will open spontaneously, and pour out thick, yellowish pus, which is caused by necrosis of the superficial tissues and destruction of bone. The ulcers do not respond to specific treatment or local applications unless the sequestrum has been removed. The necrotic areas may persist for years until sufficient necrosis takes place to loosen the sequestrum, when granulation follows. Local surgical treatment of gummatous osteitis depends on the size of the gumma and on whether or not the skin has been broken. In cases of very small gummas it is unwise to open the fluctuating areas; if the gumma is one centimeter in diameter or larger, it should be opened, the sequestrum removed, and the roughened edges curetted. In the larger exposed necrotic suppurating areas all necrotic bone should be removed, the skin edges freshened, and wet dressings applied. Sspecific treatment should be given in conjunction with local treatment.

7. Diverticulitis, Being Some Remarks Made in the Course of a Discussion at a Meeting of the Section of Surgery (Subsection of Proctology), Royal Society of Medicine, on January 7. G. Grey Turner.

1. An Address on the Application of War Methods in Civil Practice.—Sir Anthony Bowlby, after discussing the prevention and treatment of shock, the question of anesthetics, the treatment of patients with fractures, wound infection and antiseptics, expresses the belief that in the future the civilian surgeon will work even more with the bacteriologist than he did before the war, for it has been by collaboration and experiment that many advances have been maintained without risk to the patient. He warns that, as far as details are concerned, a too rigid standardization may be harmful. The only safe attitude is that one should always be inclined to believe that however good a method may be it is always possible to evolve another which may be better still. He points out that the surgery of the immediate future may well be expected to benefit from our recent experiences; that we should improve our transport service and our first-aid for the wounded in civil life; that shock can be better treated and can often be prevented; that anesthesia can be rendered safer; that no antiseptic can at once sterilize infected wounds; that in delayed suture we have an important advance in surgical technique, and that suppurating wounds can be treated by improved methods.

4. The Meaning of Tachycardia.—R. McNair Wilson calls attention to the appearance, after the influenza epidemic, of a number of cases in which a rapid pulse-rate seemed to be the chief symptom. The clinical picture was that of convalescence, a rather slow convalescence. The patients tended to be breathless and occasionally complained of feeling giddy. If their attention had been called to their pulses they usually showed anxiety at the fast rate. On the other hand, they were often quite unaware that their pulses were quick at all. Many of them were apparently well and capable of considerable exertion. Other cases of tachycardia have been met with in patients suffering from dysentery, chronic malaria, chronic trench fever, and other diseases. The chief physical sign is the quick pulse,

which may reach 120 or higher, but which is commonly between 90 and 110. This pulse quickens still further on exertion, running up often to 160, as recorded by the polygraph. Moreover, there is a normal "release" with atropine which, when given in doses of 1/33 gr. subcutaneously, produces an acceleration of 20-25 beats a minute. This normal release led to the view that the vagus nerve in these cases is normal in all respects, but evidence gradually accumulated which pointed to a different conclusion. It was found that if the patients were instructed to take a long deep breath and hold it marked slowing of the pulse or a marked loss of pulse volume with quickening was wont to occur. After atropine this phenomenon could not be elicited. Moreover, in a series of controls who had not recently suffered from any acute illness and who were not the victims of "rheumatism" no slowing and no loss of volume occurred. It was concluded that the phenomena were abnormal, and that they depended on the vagus for their production. Following this view, studies were made in augmentation and acceleration. Graphic illustrations of the findings are given. From these studies the writer was led to conclude that tachycardia in a man who is up and about is compensatory in character, the addition of acceleration to augmentation. It points to the presence of a mild infection, and can be removed only by removing the infection. There is evidence that the action of the toxin is directly on the cardiac vagus.

1. The Treatment and Management of Diseases Due to Deficiency of Diet; Scurvy and Beriberi. W. H. Willcox.
2. The Aims and Methods of Graduate Study. Sir Humphry Rolleston.
3. The Uses of Free Transplants of the Fascia Lata in Surgery. G. Grey Turner.
4. Three Acute Abdominal Cases. J. Lionel Stretton.

1. The Treatment and Management of Disease Due to Deficiency of Diet; Scurvy and Beriberi.—W. H. Willcox, who was consulting physician to the Mesopotamian Expeditionary Force (1916-1919), states that the careful investigations made in connection with these diseases in Mesopotamia, and the results of the management—that is, the scientific rationing—of the troops, have most conclusively established that both scurvy and beriberi are essentially deficiency diseases and are due to a deficiency in the respective vitamines in the dietary associated with their causation. The old idea of sufficiency of calories, or of proteins, fat, and carbohydrates, is quite inadequate. A dietary to be satisfactory must contain proteins, fat, and carbohydrates in the proper amount, and must satisfy the caloric requirements, but it is essential that, in addition, it should be adequate as regards vitamine content—for example, it must be protective against scurvy, beriberi, and other deficiency diseases.

3. The Uses of Free Transplants of the Fascia Lata in Surgery.—G. Grey Turner, in using the term "free transplants," refers to a portion of fascia lata removed from the thigh of the patient for use in some remote part of his own body. He has used the method in arthroplasty of the elbow and in the jaw joint, with very satisfactory results, and calls attention to its uses under other circumstances which are perhaps less well known. It is valuable for protecting the deeper structures, such as sutured nerves or tendons, during the slow healing of a wound by granulation, or when the superficial tissues are so much damaged that their recovery after suture is likely to be attended with sloughing. It is also exceedingly useful for the replacement of lost tendons. Transplants are also useful to cover exposed brain, where the membranes are deficient, thus preventing it becoming adherent to the scalp. Similarly, fascia lata may be used for repairing the urethra. The writer has had no trouble associated with the area from which the flap is cut. He always exposes it through a vertical incision on the outer side of the thigh, and, except where the transplant has been a very small one, he does not resuture the fascia. He has seen no trouble from the break in the covering of the thigh muscles, though the patients sometimes complain of soreness and aching in that area for a time.

1. Everyday Problems in Conserving the Hearing. William S. Tomlin.
2. Nasal Syphilis, with Case Report. A. Wade Thrasher.
3. Pathological Conditions Caused by the Impaction of Teeth. Charles A. Barnhill.
4. Medicine: An Art, a Science, a Trade? James C. Carter.

1. Everyday Problems in Conserving the Hearing.—William S. Tomlin reminds the reader that the prophylaxis of the hearing organs in comparative health comprises principally the hygiene of the nose and throat and mouth, together with instructions in the proper ways of performing daily functions or ordinary cleansing of these parts. In this connection he calls attention to the incorrect use of the handkerchief by the average adult, the nose being constricted instead of permitting free egress of the compressed air. The extraordinary compression at such times, coupled with the present infection and swelling around the eustachian tubes, is a baneful source of acute otitis media. Both children and adults with colds and other infections known to be active in the epipharynx should be required or encouraged to lie on the sides instead of on the back, the latter position bringing gravity in effect towards the tympanum. Faults of ventilation and drainage in the upper air passages constitute the most important menaces to the hearing organs. Inequality in the lumina of the nostrils, with resulting imbalance of atmospheric pressure, and, added to this, projections and pockets, producing whorls in the passing air, with friction here and deposits of bacteria-laden dust there, bring about an endless chain of pathological possibilities and probabilities, with a cloudy future for the hearing apparatus of the individual in a large percentage of cases. Whether hypertrophied adenoids, indurated or hypertrophied tonsils, or other conditions cause imperfect ventilation of and lead to the inflammatory material toward the tympanum and mastoid, such faulty mechanism must be corrected if infection is to be prevented. The damage to the organs of hearing in consequence of "just a cold" cannot be gainsaid, the acute cold giving rise mostly to acute types and the chronic and recurrent cold causing the chronic catarrhal salpingetic type of aural disturbance. Prophylaxis having failed to prevent otitis media, it then becomes necessary to combat the existing conditions, to endeavor to prevent further damage, and to see that the prime factors which have brought about the condition are not allowed to continue for future repetition. This may involve paracentesis, the use of vaccines, mastoid operation, or other measures according to the circumstances of the given case.

2. Acute Cholecystitis in Children as a Complication of Typhoid Fever.—Mont R. Reid and J. C. Montgomery were prompted by a case recently admitted to the Johns Hopkins Hospital to make a review of the cases of this nature which have been reported. Altogether they collected 18 cases of typhoid fever in children under the age of 15 who either died from, or were operated upon for, complications arising in the gall-bladder. These cases are briefly reviewed and are also given in tabular form. In one case (No. 11) of this series the acute cholecystitis did not develop until

eight months after recovery from the disease; in all the other cases the complications came on during the course of the disease. Eight patients died without operation. All of these cases were reported prior to the year 1893. Since that time 10 cases which have been treated surgically have been reported. One of these patients died—a mortality of 10 per cent. The records of the earliest cases are not supported by any bacteriological studies. In recent years cultures of the gall-bladder have usually been made at the time of operation. In this connection the leucocyte count is of interest. When the cultures have shown a pure culture of the typhoid bacillus the count has been relatively low, usually about 10,000. In one case of the series (No. 12), in which cultures were not made, there was a leucocyte count of 33,000, and in another (No. 15), which showed an organism not definitely identified, there was a count of 21,000. Six cases of the series reported were admitted to the Johns Hopkins Hospital; all were treated surgically, and all recovered. Cholecystostomy was performed in five and chloecystectomy in one of these six cases. The good results obtained in recent years are due to the fact that the operations have been performed before rupture of the gall-bladder and partly also to better surgical treatment. The writers emphasize the importance of differentiating between gall-bladder complications that do and those that do not require surgical treatment. Slight pain and tenderness in the region of the gall-bladder, associated with a slight degree of spasticity of the right rectus muscle, are not so very unusual during the course of typhoid fever. The vast majority of these patients get well. Operating on typhoid fever patients for minor symptoms of cholecystitis is probably only slightly less justifiable than operating upon all patients that have pain in order to prevent intestinal perforation. Nevertheless, the low operative mortality justifies operation when there is grave doubt as to the nature of the condition of the gall-bladder. Acute suppurative typhoidal cholecystitis should receive immediate surgical treatment, for in such cases rupture of the gall-bladder may occur, and thus lessen many times the chances of recovery. The writers believe that the best treatment is cholecystectomy.

7. **A Case of Non-Parasitic Hæmatochyluria.**—H. H. Hampton, resident gynecologist of the Johns Hopkins Hospital, bases his study of this subject upon the case of a woman, 23 years of age, from the mountains of Virginia, admitted to the clinic in August, 1919. Careful study of the case showed that it is one of non-parasitic chyluria that has persisted over a period of nine years in a young woman whose health is below par. She has a mitral stenosis that has given symptoms at intervals for more than ten years. Her chief complaint has been general weakness with frequent syncopal attacks. Just how much of her disability has depended upon one or other of these conditions, it is difficult to say. Apparently her kidney function is unimpaired. There is no evidence of renal or pulmonary tuberculosis. The leak in the lymphatic system is located in the right kidney. Upon starvation or a fat-free diet, the urine becomes fat-free, blood cells and albumin persisting. Posture influences but does not control the amount of lymph leakage. Increased water intake and urine output increases the "fat loss." The leakage of lymph in most chyluria cases is located in one or both kidneys and location of this connection in the ureter or bladder should be made with caution. The connection between the lymphatic and urinary systems, which is usually located in the kidneys, probably consists of ruptured varicose lymphatics belonging to the deep lymphatic system of the kidney. Lymph fistulæ, wherever they occur, are generally associated with mechanical blockage of the large trunks or thoracic duct.

3. Beriberi Among the Chinese in France. A. R. Leggate.

3. Beriberi Among the Chinese in France.—A. R. Leggate had the opportunity, in 1917, when the Chinese were arriving in France, of studying 269 cases of beriberi in the Chinese General Hospital. There are two types, the wet and dry. In the former the first symptom is anasarca. Every part of the body may be edematous, but the edema is most easily detected and usually most severe in the lower limbs. In the latter there is no edema whatever. The view that the occurrence of beriberi was intimately associated with a diet in which polished rise bulked too largely was supported by the writer's observations. Beriberi is one of the many types of peripheral neuritis, and one of its peculiarities is that it is usually, not always, associated with edema. The three main symptoms of the disease are edema, loss of deep reflexes, and paresthesia. Paresthesia takes the form of numbness and formication, sometimes the former only, less often the latter only, but usually both. Diarrhea, cardiac weakness, dyspnea, and other symptoms may occur. In uncomplicated cases there are no febrile symptoms, no loss of appetite, and no quickening of the pulse. Inability to rise from a squatting position is a symptom usually confined to the dry type. In the coolies who are fed mainly on polished rice the disease may show itself in from forty to fifty days. An important part of the treatment consists in discontinuing polished rice diet, and administering yeast, eggs, beans, and peas, and in the edematous type, purgatives.

Il Policlinico

Atropine in General Diagnosis.—Siciliano refers to the action of atropine instilled into the eve in the diagnosis of the autonomous nervous system. The pupil may be likened to the heart in this respect. The duration of the action of the drug on the pupil is of much significance in this connection, and also the action of the large as well as small dose. One eye only is used in the test, the other serving as control. One drop of a 1 per cent. solution is first instilled and the time of dilatation noted for each eye, as well as the amplitude of the pupil and the time of return to the *status quo ante*. The author attempts to establish a scheme as follows: If the iridoconstrictor (motor oculi) innervation is intense and the sympathetic innervation slight there is notable augmentation of the pupillary diameter without extreme dilatation, while duration of dilatation is brief and return rapid. On the other hand, if sympathetic innervation is intense and motor oculi innervation slight we see the maximum of dilatation with slow return. Should both innervations be slight dilatation is of low degree and return slow, while if both are intense there is a maximum dilatation with rapid return.

Le Progrès Médical.

November 29, 1919, xlvii, 48.

Arterial Pressure in Anxious States.—Euzière and Margarot refer first to the rôle of the sympathetic in anxious syndromes. Recently the question has been brought up in connection with psychic phenomena on the one hand and internal secretions on the other. The authors have become convinced that in anxious states sympathicotonus is increased. Thus the oculocardiac reflex is inverted or abolished, the tendon and masseteric reflexes are quickened, and there are a slight hyperglycemia, anorexia, dry mouth, constipation, tachypnea, cardiac acceleration, and, finally, elevation of blood pressure. The latter has been especially studied. There are two classes of hypertensives, in one of which there is nothing to account for the increase, while in the other there is some other factor which makes for this increase. In the second class, therefore, the anxious state aggravates a condition already present. Measurements were taken in subjects with primary or constitutional anxious states, anxious psychoses and melancholia. The increased tension was transient, and when the mental state subsided the tension fell. As implied the phenomenon is not an isolated one, but part of the syndrome of sympathicotonus. It is not claimed that the increase in tension reaches any unusual figures, but simply that there is a marked rise from tensions which seem to have been rather low than high.

Book Reviews.

THE NUTRITION OF THE FETUS. By J. MORRIS SLEMONS. New Haven: Yale University Press, 1919.

THIS is the Oration in Obstetrics delivered at the annual meeting of the Ontario Medical Association held in Toronto, in May, 1919, and is reprinted from the *American Journal of Obstetrics* for August, 1919. The work is based upon investigations made by Dr. Slemons and others in the Department of Obstetrics and Gynecology in the Yale Medical School through the use of the Julia E. Brooker fund. It is not necessary to analyze the work here, for this the reader can do for himself. It is very suggestive, however, and will well repay perusal. While not setting forth any novel theories of fetal nutrition, Dr. Slemons gives an excellent summary of what is known on the subject, and disposes of several misconceptions held by some medical men as well as by the laity.

THE OXFORD MEDICINE ADVANCE PAGES. Edited by HENRY A. CHRISTIAN and Sir JAMES MACKENZIE. Vol. II, Part 1. New York: Oxford University Press, American Branch, 1919.

THIS part contains three chapters dealing respectively with "Diseases of the Heart," by Sir James Mackenzie; "Bronchial Asthma," by J. Chandler Walker, and "Hay Fever," by the same. The first article fills 112 of the 149 pages and is one of the most valuable contributions that has appeared in the work thus far. Those familiar with the author's views on the heart and its diseases, views which have received wide acceptance and have greatly modified our conception of these affections, will find them restated here in new and very lucid terms. Not the least of Sir James Mackenzie's services to mankind has been the quieting of the terror formerly inspired by the term "heart disease," a terror which he has shown to be in many cases groundless.

The chapter on "Asthma" by Dr. Walker is most illuminating and one that can be read with profit by the general practitioner of an earlier generation who is not as familiar as he should be with the rôle of protein sensitivity in the causation of this malady. The article on "Hay Fever" by the same author is treated along the same lines, the disease being regarded as a manifestation of anaphylaxis, and susceptible of cure by the same method as is employed for the relief of bronchial asthma.

THE URETHROSCOPE IN THE DIAGNOSIS AND TREATMENT OF URETHRITIS By Major N. P. L. LUMB, O.B.E., R.A.M.C.(T.C.). A contribution to Urethroscopy. Illustrated by 40 original illustrations. New York: William Wood & Co., 1919.

THIS little book has but 47 pages of text, but this is ample for the purpose because but little space is devoted to apparatus, the author merely describing and figuring the Wyndham-Powell urethroscope which has an air dilatation attachment. By reason of the large number of colored plates the work is virtually an atlas, the text tending to follow the plates rather than the plates the text. Thus visualized, the work is an excellent one. Short histories of some of the cases illustrated by the plates are given. No less than 12 of the 40 plates are devoted to the normal urethra. The more one looks into the book the better it pleases.

THE PREVENTION OF DENTAL CARIES AND ORAL SEPSIS. By H. P. PICKERILL, M.D., Ch.B., M.D.S. (Birm.), L.D.S. (Eng.), Professor of Dentistry and Director of the Dental School in the University of Otago. Second edition. New York: Paul B. Hoeber, 1919.

ALTHOUGH this is a second edition, the work is practically a new one to American readers, and indeed the amount of new matter included in it would make it of value even to those possessing the earlier edition. This new matter consists of accounts of the author's investigations into the bacteriology of the mouths of immune Maori children, the anatomy and physiology of mastication, thyroid insufficiency and dental caries, and the relationship between oral and other alimentary secretions. There is much in the book of great interest to practising physicians as well as to dental surgeons, for every day the dividing line between the two professions is wearing thinner. One very interesting chapter is that on the diet of races relatively immune to caries, in which the author shows that, contrary to the general belief, meat eaters are more subject to caries than those who are largely or wholly vegetarians, and that the most immune are those who use sapid and highly seasoned food and are given to mastication, thus stimulating the secretion of alkaline saliva. Dr. Pickerill urges that the medical curriculum should include a short course on stomatology and should receive practical instruction in the relation of diet to caries, especially during childhood. By starting the children in his clientèle on a correct diet he will go far toward saving them from much dental misery.

HALF A CENTURY OF SMALLPOX AND VACCINATION, Being the Milroy Lectures delivered before the Royal College of Physicians of London on March 13, 18 and 20, 1919. By JOHN C. MCVAIL, M.D., LL.D. Edinburgh: E. & S. Livingstone, 1919.

THIS volume is the fifteenth contribution which the author has made to the subject of smallpox and vaccination, and comes somewhat in the nature of his valedictory. For this reason, as he states in the preface, he has endeavored in the first lecture to survey the statistical and epidemiological history of smallpox in modern times. The second lecture is largely devoted to a rebuttal of the contention that infantile vaccination, while protecting the individual, makes smallpox so mild and so difficult to recognize where it is not entirely prevented, that the result is such a spread of infection from missed cases as to render the practice, on balance, disadvantageous to the community. The final lecture gives an account in considerable detail of the measures of prevention and control which, in the absence of systematic vaccination and revaccination, ought, in the author's judgment, to be adopted when the disease appears. A list of the author's previous contributions is appended to the preface. The last six of the 86 pages of the volume are devoted to correspondence concerning some of the views held by the author.

THE EXACT DIAGNOSIS OF LATENT CANCER. An Enquiry into the True Significance of the Morphological Changes in the Blood. By O. C. GRUNER, M.D., Author of "Biology of the Blood Cells," "Studies in Puncture-Fluids," "A Code System in Pathology," etc. Philadelphia: P. Blakiston's Sons & Co., 1919.

THE author devotes 79 pages, with 19 illustrations and 21 tables, to answering two questions which, as he states in the preface, sometimes arise in practice: (1) The patient or the friends ask if there is any further test for cancer by which to become quite sure that an operation is really inevitable; (2) the surgeon himself desires to know if his patient is really free of disease after an apparently successful operation. The author holds that the answer is obtained by ascertaining, from a close study of the blood, whether or not the patient is a substrate compatible with the presence of cancer. The process of arriving at a diagnosis of latent cancer involves the preparation of the patient, the collection of the material, the study of the material, the records of findings, and the building of an opinion. The degree of exactness of diagnosis of a blood state, whether it be cancerous or any other, is limited solely by the time and care bestowed upon it, by the clearness of the law of the blood cells, of the law of continuity in pathology, and by the broadness of conception which one is willing to hold in respect of problems which progressively unfold themselves as one proceeds.

LA MÉNINGITE TUBERCULEUSE DE L'ENFANT. Par le Dr. A. LESAGE, Médecin des Hôpitaux de Paris, Membre du Comité supérieur de protection des Enfants de premièr âge. Paris: Masson et Cie., 1919.

IN this small book Lesage has included a very complete discussion of tuberculous meningitis, especially as it concerns infants of less than two years. It has not been generally recognized that children of this age are often affected with this disease, but the author has had an unusual experience in this respect and feels that the small figures reported by other investigators are possibly due to incomplete or imperfect observation. There is nothing new or startling in this monograph, but it is very complete and will be found to make interesting reading.

Society Reports.

SOUTHERN SURGICAL ASSOCIATION.

Thirty-second Annual Session, Held at New Orleans, December 16, 17, and 18, 1919.

THE PRESIDENT, DR. JAMES E. THOMPSON OF GALVESTON, TEXAS, IN THE CHAIR.

The Injection of the Gasserian Ganglion for Neuralgia and Other Conditions.—DR. CARROLL W. ALLEN of New Orleans, said that the proper execution of the technic of this injection demanded a thorough knowledge of the osteology of the parts involved, also of the soft parts below the floor of the skull and within the skull adjacent to the foramen ovale, and the effects upon these internal parts of the alcohol injected. This information was acquired only by diligent study and extensive clinical experience. The method most commonly used and the one practiced by him almost exclusively was the Härtel route. This had as its external landmarks the point of entrance of the needle, which was within an area on the cheek opposite the three upper molar teeth; in many cases these teeth had been extracted in efforts to obtain relief, but their former position was easily determined. As the foramen ovale was a fixed point behind and above this area on the cheek, when the needle was entered opposite the first molar it naturally had to follow a more oblique course and traversed a greater depth through the soft parts than when entered opposite the last molar tooth, which was more nearly under the foramen ovale. As the needle which was used was long and slender, its point could be more accurately manipulated when advanced through the shorter route and the difficulties encountered were often less, as the route passed through some muscle, the contraction of which served to deviate its point, and this was more marked in the longer route. It had been found that chromium sulphate exerted a curative influence on the keratitis which sometimes followed these injections. Accordingly, he had been giving all of his recent cases a four grain tablet of this remedy three times daily as a prophylactic, advising its use for about one month. In his last twelve cases there had been no evidence of eye inflammation. From his experience, he was convinced that when the value of these injections for these conditions was recognized, they would be extensively used, as any method which afforded such marked relief was a blessing to these unfortunates in allowing them to retain their mental faculties unclouded by morphin until the disease had advanced to such a point that narcotic oblivion was to be preferred.

Gunshot Wounds of the Brain with Retained Missiles.—DR. CHARLES BAGLEY, JR., of Baltimore, stated that during the spring and summer of 1918, 175 cases of gunshot wounds of the skull and brain were studied at the General Hospital No. 2, Baltimore. Of these cases 80 required one or more operations. The total number of operations performed was 108. In this series there were 9 patients with metallic foreign bodies in the brain substance. Of this number, 7 cases were operated on for the removal of the foreign body, one case was discharged without an attempt at removal because of the small size of the missiles and their position in the brain, and the fourth case with a metallic foreign body in the right cerebellar peduncle died as a result of an abscess in the occipital lobe, although no attempt was made to remove the metallic foreign body. Removal of the foreign bodies was undertaken because of the presence or probability of infection. In one case, with a machine gun bullet in the right cerebral hemisphere, there was a small abscess which contained staphylococcus pus. In another there was a large abscess in the left temporal lobe, which also contained a staphylococcus pus. In two others the foreign bodies removed at operation gave positive staphylococcus cultures. The foreign bodies removed from the three remaining cases gave negative cultures. He was of the opinino that because of the likelihood of metallic foreign bodies of average size giving trouble even several months after the injury, they should be removed if their removal did not offer too great difficulties. He recognized, however, that metallic foreign body substances might remain encapsulated in the brain substance without giving trouble, and he gave as an illustration of this the case of a civilian in whom a large lead bullet had remained in the left occipital lobe for ten years. Of the operative cases of the series, all had recovered, or were at this time convalescing.

Spermatoceles and Hydroceles Containing Spermatozoa.—DR. RANDOLPH WINSLOW of Baltiuore stated that the occurrence of 6 cases of hydroceles containing spermatozoa, and of one of true spermatocele associated with a hydrocele, at the University Hospital, Baltimore, in the course of a few months, had directed his attention to this condition. In the cases of which he had notes, no mention was made of an injury, except in one instance, that of a man, 55 years of age, who was struck on the scrotum when he was a boy. He had had a hydrocele for 40 years, but there was no way of determining how long the spermatozoa had been present in the sac. He thought it probable that in some cases, at least, true spermatoceles ruptured into hydroceles and in that manner permitted the ingress of spermatozoa into the sac of the tunica vaginalis. In one case there was a hydrocele with clear contents and contiguous to, but not communicating with it, was another cyst containing a milky looking fluid, which showed spermatozoa when examined with a microscope. This cyst might have ruptured into the hydrocele if it had remained longer unoperated. The treatment of true spermatocele was usually excision, while that of the hydrocele containing spermatozoa was similar to that of ordinary hydroceles, namely, excision of the tunica vaginalis or suturing the tunica behind the testicle, or Andrew's bottle operation, etc., and the results appeared to be equally as good as those of uncomplicated hydroceles.

Hypodermoclysis.—DR. WILLARD BARTLETT of St. Louis stated that when continuous hypodermoclysis was used, the visible dropper and screw clamp were added. An attempt was made to get gravity pressure by placing the container directly above the patient. As to the fluid employed, Dr. McKittrick proposed plain, freshly distilled water. In view of the large amounts of fluid instilled, and the harmful effects which occasionally followed the absorption of abnormal amounts of sodium chlorid, he did not countenance its use, especially in patients already weakened by disease or surgical trauma. The water was heated to between 100° and 110° F. and then poured into the warm container. The slender needle was first thrust through the center of a square fold of gauze and was then ready for use. This prevented the hand touching the needle or contaminating the skin, which had been cleaned with alcohol, and painted with iodin diluted one-third its strength with alcohol. The fluid was then started through the tubing, and when all air had thereby been expelled, the tubing was temporarily pinched off with the thumb and finger, and the operation begun. In unconscious patients, the needle was plunged up to its flange in the subcutaneous tissue, at a point near the outer border of the pectoral muscles, midway between the nipple and the head of the humerus. By this method, the fluid extended directly into the subcutaneous tissue of both the axilla and the breast. Absorption was almost twice as fast as it was when the injection was under the breast alone. The needle was held in place by a strip of adhesive, the original piece of gauze being utilized to prevent contamination of the needle wound. If the needle remained in very long, alcohol was dropped over this region from time to time, and gauze was then placed over the exposed portion of the needle, adhesive and all. A hot water bag, wrapped with a towel, was placed directly under the axilla, and another one over the gauze, which protected the needle. The fluid should not run in so fast, but what with the aid of the hot water bottle the tissues, although very slightly edematous remained soft and pliable. Only the one side was used at a time regardless of the amount of fluid to be infused. Usually 800 to 1200 c.c. was given during one injection, though a much larger amount could be given if it was allowed to run in slowly. Between one and two hours was all the time needed in the ordinary case, and frequently one hour was sufficient, this differing with individuals. The giving of hypodermoclysis was easily accomplished without pain or distress in

most patients not under the influence of a narcotic. The procedure had completely supplanted the rectal administration in his service, and where intelligently applied, seemed not to have unduly disturbed the patient, had never been attended by an accident, and had given the greatest satisfaction.

Shoes.—Dr. Robert Carothers of Cincinnati said that the very great majority of adult Americans had some defect or acquired deformity of their feet. Abnormal feet were responsible for many of the other defects in their anatomy, and in many and most instances the foot deformity was caused by ill-shaped and incorrectly designed shoes. There was an old saying that when your feet hurt, you hurt all over. It might as truthfully be said that when your feet were deformed, there was likely to be some deformity elsewhere in the body. How frequently we found one knee sprung and bucked knees associated with and relieved by correcting flat feet. Almost as frequently did we observe some abnormality of the lumbar and sacroiliac regions caused by bad feet, and occasionally round shoulders were corrected by better feet. It was quite necessary for one to have good feet, that he might have good joints elsewhere, and that the framework of the body should be correct, and the musculature of the body be well developed. An examination of many athletes would prove this statement. Was it not possible and necessary for an individual to have good feet, good joints and well developed muscles, especially of the back and abdomen, to prevent a visceroptosis? It was.

Empyema at the Cincinnati General Hospital During the Influenza Epidemic.—Dr. Joseph Ransohoff of Cincinnati drew the following conclusions: (1) It is not the empyema which kills when it is a complication of influenza. Too early operative measures are to be avoided and to be limited to simple aspiration. (2) Operations done not earlier than the end of the second week give the best results. Rib resection is indicated only when insufficient room is at command without it. (3) General anesthesia is not necessary in most cases, but from our experience does not increase the mortality of the operation. (4) The old methods of drainage should be given up for some type of the occlusion method, by which the entrance of air into the pleural cavity is prevented and the egress of pus facilitated. A suction apparatus attached to the tube we deem unnecessary. (5) Flushing of the cavity with Dakin or other solution is unnecessary, except when defervescence does not occur, thereby indicating that the spontaneous sterilization of the cavity is not progressing normally. (6) The small pneumothorax which sometimes remains after the healing of a cavity, as has been demonstrated by the *x*-ray, is negligible, since it disappears spontaneously in a short time. (7) Twenty of the operations were performed by myself, the remainder by various attending surgeons of the hospital, to whom I am greatly indebted for carrying out the suggestions which I believed were essential in securing so low a mortality in the treatment of our empyema cases. (8) The fact that we were enabled to secure end results in all but 8 of our cases shows one of the many advantages of an efficient hospital social service.

Pseudomyxoma Peritonei.—Dr. M. H. Biggs of Ruthcrfordton, N. C., stated that pseudomyxoma peritonei had received but scant recognition by American obscers or writers. It resulted from the rupture of a pseudo-myxomatous cyst of the ovary or appendix, the epithelial cells thus discharged being implanted on the peritoneum and producing pseudomucin and tumor formation. It was originally believed to be secondary to a cyst of the ovary, but was now known to originate also in the appendix. The pathology of the condition was reviewed, and the author considered that it resulted from cellular implantation. Failure of this condition to result from rupture of a pseudomyxomatous cyst, as must often happen, was explained by infrequent rupture of the smaller loculi which contained active cells, but cells that were firmly adherent to their basement membrane; and to thinning of the walls of the larger loculi, the cells at the point of rupture being poor plants. The symptoms were those produced by mechanical interference with function. The findings at operation varied from a small amount of jelly-like material with irritation of the peritoneum, to a large quantity of thick, tenacious material and secondary tumor formation of the peritoneum covering the abdominal viscera. The author described a fine pebbly appearance of the peritoneum which he considered the early stage of pseudomyxomatous development. Age was an important diagnostic factor, the lesion occurring in advanced life, after the menopause in the female, at a time when many other conditions could be excluded. The average age in his cases was over sixty years. At operation it was important to remove all the original growth. When this was done, and a careful toilet of the peritoneum made, early cases might be cured. The following were the author's conclusions: (1) This condition is much more frequent than is generally recognized. (2) It is caused by cellular implantation. (3) It is histologically benign, but may be clinically malignant. (4) If it is considered to be a form of cancer, it must be assumed that pseudomucin inhibits its destructive power. (5) It may originate in the ovary or the intestinal tract; ovarian origin being by far the most frequent. (6) If it is appendiceal in origin, the appendix has been the seat of chronic inflammation. (7) Early invasion of the peritoneum is characterized by a pebbly appearance. (8) In early cases the condition will sometimes be cured, and at any stage it may be inhibited, by operation.

Pseudomyxoma Peritonei in Male Subjects.—Dr. M G. Seelig of St. Louis said the most striking, outstanding and characterizing feature of the disease was the accumulation in the peritoneal cavity of a colloid exudate, varying in consistency from a syrup to solid colloid masses. This exudate was the only constant accompaniment of the disease. In some instances there was a progressive cachexia, leading to death; in others the disease ran a benign course with perfect recovery after suitable operative procedure and often doubtlessly without operation. In the vast majority of cases the primary cause of the disease was the rupture of a pseudo-mucinous ovarian cyst. In a by no means small minority of the cases the cause of the rupture was a mucocele of the appendix. Up to date the latter cause was the only one that had been found to be responsible for the disease as it occurred in males. In some cases the colloid material was confined in loculi whose walls were made up of a connective tissue new growth so firm and abundant that it fused all the viscera into a solid mass, molded, as it were, into the peritoneal cavity. Some authors considered this process as a type of plastic foreign body peritonitis; others considered it as secondary myxomatous degeneration of the peritoneum; others as multiple cystic lymphangiomata; others as a type of innocent implantation metastasis; others as frank carcinosis peritonei, and still others as a specific type of peritoneal infection producing mucin. The important fact was that the appendix itself was the sole responsible agent for the disease as we encountered it in the male. Treatment consisted in removing the primary focus of disease—the appendix, and scouping out that portion of the exudate which could be reached conveniently and with safety, without any attempt to clear the abdominal cavity of its entire pseudomucinous contents.

Congenital Diaphragmatic Hernia With Report of a Case.—Dr Louis Frank of Louisville stated that a careful review of the literature since Scudder's paper revealed only 41 additional cases reported, and one of these a personal communication. He was forced to believe from conversation with some of his *x*-ray friends. that there had been others, but whether they occurred in adults, or whether they ever came to operation, he had no means of knowing. Of the additional cases recorded in the literature, only 5 were reported as congenital, those observed and operated on being accounted for largely by the trauma of war. Most of the cases occurred in soldiers as the direct result of missiles. In this type of case the hernia was almost uniformly on the left side. A study of these cases indicated that the abdominal method of approach was the most popular. This was easy to understand in the cases of traumatic origin where a missile had entered the abdomen primarily. He found also that one patient with congenital hernia was subjected to gastroenterostomy, this being the only feasible procedure to obtain relief from urgent symptoms which were present. Of the

additional cases which he had collected, two were observed post-mortem. One was advised against operation, the pathology having existed without much discomfort, according to the history, for a period of 45 years, the patient at the time of diagnosis and presentation being 59 years of age.

A Warning Against Promiscuous Uterine Curettage.—Dr. J. WESLEY BOVEE of Washington, D. C., said it was well to point out the many dangers incident to uterine curettage. Not infrequently was a pregnancy in its first month thus scraped from the uterus and perhaps never recognized. Certainly humiliation had often come to the operator by discovering during curettage that an unsuspected pregnancy had been interrupted. Very often pregnancy had unnecessarily been ended by curettage for incomplete abortion. The literature teemed with reports of cases of perforation of the uterus by the curette with or without dangerous sequelæ and even death. The cervical canal was so constantly infected that it did not seem strange infection might be carried from it into the uterine cavity by the curette, sound or dilator. Again, it was shown by Curtis that infection of the endometrium was nearly always associated with similar infection of the tubes and most often gonorrheal. Curettement under such conditions was strongly contraindicated. The dangers from curetting were ever present, whether in the hands of the skilled surgeon, or of those of the less fortunate confrère, or of the midwife, and should be practically excluded from the infected uterus. If chronic endometritis as a clinical entity was to be ruled out, one potent indication for curettage in the past would be removed.

The Operative Treatment of Pelvic Inflammation.—Dr. CHARLES R. ROBINS of Richmond, Va., read this paper, of which the following were the conclusions: "(1) Pelvic inflammation is most frequently due to one of two causes, gonorrhea or infections following abortion or labor at term. (2) These two types differ widely as to methods of treatment. Gonorrheal cases are, as a rule, local in their effect and are not attended by symptoms of absorption, Infections following abortions or labor at term, on the other hand, always manifest symptoms of intense absorption and are of the nature of a septicemia. (3) Operation on gonorrheal cases may be performed with comparative safety at any stage, but radical operation on the septicemic group in the acute stage is attended by a high mortality and should not be done. (4) Delay in operation on the septicemic group is an advantage, is less dangerous and often results in symptomatic or absolute cure. (5) The best method of treatment is that usually known as Fowler, Ochsner-Murphy treatment. (6) The cases in which operation is indicated are those which have passed into the chronic stage, but a moderate delay is permissible. (7) In operation it is seldom practicable to restore the function of the tubes. They really become the foci of infection, their removal stops the toxic process, and if they are left further trouble is liable to manifest itself. (8) The objects of the operation are to remove the tubes and preserve the essential organs of menstruation, the uterus and the ovaries. (9) The details of operation on which emphasis is laid are the complete removal of the tube by excising also the uterine portion, the attachment of the broad ligament to the horn of the uterus, thereby elevating the ovary away from pressure and adhesions and the temporary suspension of the uterus."

A New Suspension Operation for Retroversion of the Uterus.—Dr. F. G. DUBOSE of Selma, Ala., said this operation had given uniform satisfaction in more than 50 operated cases, without a failure in any instance to correct and hold in position the retroverted uterus. The following was the technique which he employed: A linen or silk thread on a full curved needle was run through the broad ligament close to and immediately underneath the round ligament, beginning at the internal abdominal ring, carried across the fundus of the uterus under the peritoneal coat, passing underneath the opposite round ligament until the other internal ring was reached. The needle was unthreaded and a ligature carrier was passed through the aponeurosis of the rectus muscle about an inch from the abdominal incision and on a level with the internal abdominal ring through the musculature of the anterior abdominal wall until it emerged from the parietal peritoneum at the internal abdominal ring. The linen suture was threaded on this carrier and drawn through the abdominal wall. The same technique was carried out on the opposite side; then both ends of the thread were caught and the uterus pulled up to the desired position. Two hemostats were then applied to the thread, one on either side, where it emerged from the aponeurosis of the rectus muscle. The peritoneum was then closed, the aponeurosis of the rectus muscle sutured, and while the forceps were still in position the linen suspension thread was tied. The placing of the forceps prevented the drawing too tightly on the suspension suture, which would bring the uterus too far forward and possibly so narrow the space between the uterus and abdominal wall as to result in hernia of the intestines or obstruction. The hemostats were removed after tying the suspension suture. The closure of the abdominal skin incision was then completed.

Unraveling the Mysteries of Right-Sided Abdominal Pain in the Female.—Dr. JAMES N. BAKER of Montgomery, Ala., stated that the most important step in the efforts to arrive at sound conclusions was the history, carefully and sequentially recorded by the surgeon himself, and going back to the very beginning of the trouble. Careful search must be made in this long trail for acute "flare-ups," the proper interpretation of which would oftentimes serve as valuable guide posts. Was the acute condition attributable to the appendix, to the tube or ovary, to a renal colic, to a pyelitis, to a ureteral stone or stricture? A painstaking history seldom failed to reveal one or more exacerbations which pointed the way to the organ involved. One should always hesitate to hold responsible an appendix for chronic right-sided pain whose history did not unfold definte acute attacks; nor should too much importance be attached to the *x*-ray findings of a distorted and stagnant appendix whose history failed to reveal either acuteness or reflex digestive disturbances. The reverse pathological condition might obtain. Instead of a ptotic and dilated condition of the cecum, one might encounter a maldescent or partial rotation of the cecum, which was bound down and otherwise distorted by bands, either congenital or acquired, or both. This gave the picture familiarly known as Jackson's veil or Lane's kink. Here also the appendix might show inflammatory changes, but could not be held primarily responsible. It was to this class of patients that most careful study should be given. The employment of both the *x*-ray and the cystoscope was mandatory. If the genitourinary tract could be shown to be free from pathology, then, and not until then, was one justified in making his attack upon the intestinal tract. The mere removal of an appendix might not bring relief. This was evidenced by the host of sufferers still clamoring for help and who presented neat scars over McBurney's point. Liberal incisions should be employed, a careful survey of the entire area made, and all needed surgery applied.

Stone in the Kidney.—Dr. CHARLES H. MAYO of Rochester, Minn., said that stones formed in the cortex, in the calices, and in the pelvis of the kidney. The kidney was constantly eliminating living bateria, so that it was always exposed to infection, and usually showed no results from it except gross lesions of rare occurrence. Stone formation might proceed with exceeding slowness, and without pain or other symptoms until marked destruction of the kidney occurred, mixed infection developed, or until the stone assumed great size or became loosened and moved into the ureter. Minute infarctions occurred, as shown at necropsy following death from an acute attack, and the results of similar lesions in the past were shown by scars or gross kidney change. Stone formation was evidently the result of the combination of two types of bacteria; the first created an infarction with minute necrosis causing mucoid exudate to form; the second factor was the elimination at the same time of the stone-forming bacteria that might come in contact with the mucoid material. If the stone originated in the cortex of the kidney, its growth would be slow, but if it originated in the calices or pelvis, growth might be much more rapid because of the ease with which its chemical material was secured.

The Results of Operations for the Removal of Stones from the Ureter.—Dr. E. S. JUDD of Rochester, Minn.,

stated that stones in the ureter might pass voluntarily into the bladder. In his experience 12 per cent. of a group of 400 persons had admitted the passing of stones. Most of these calculi originated in the calices and in the kidney pelvis, although in some cases they might arise in the ureter in association with ureteral stricture. Stones might be lodged in the ureter and produce no symptoms and again they might produce the classic syndrome of ureteral calculus. The diagnosis, however, should always be checked up by the *x*-ray and cystoscope, using ureterograms as advocated by Dr. Braasch. After the diagnosis was established, if the patient was having frequent and severe attacks of pain, it seemed advisable to observe him for a time, knowing that a certain percentage of stones would be passed. The possibility of severe pressure in ureter and kidney, resulting in a hydronephrosis or pyonephrosis, must not be forgotten. In cases in which stone was apparently causing no symptoms, it seemed advisable to remove it unless there were contraindications. There were two methods of treatment, the nonoperative and the operative. The first method consisted in the dislodging of the stone by a ureteral catheter or small sound. The contraindications to this procedure, as given by Braasch, were: (1) A stone 2 cm. or more in diameter; (2) acute ossification with continuous obstruction; (3) acute renal infection; (4) the patient's intolerance to cystoscopic manipulation, and (5) anatomical deformity. Braasch had had excellent results in recovering these stones, especially when they were lodged at the ureteral orifice. He used instruments and papaverin. A stone lodged in the ureter might lead to marked dilatation of the ureter above the stone and to hydronephrosis. On the other hand, there might be no changes in the ureter and kidney above the stone. The latter type of stone was small and difficult to locate. The kidney should not be removed unless extensively infected, as it might recover its function. If pyelonephritis had resulted from the stone and there was evidence of general infection, if the opposite kidney functionated well, it was inadvisable to remove the stone. If the stone was in the lower third of the ureter and kidney was badly damaged, it was better to remove the kidney and leave the stone. The stone might have to be removed later because of pain. When the stone obstructed the ureter so that the function of the kidney on the same side could not be ascertained it seemed best to remove the stone only. Conservative methods were justified in any case of chronic kidney infection, while radical methods must be employed in acute, severe infections. Nephrectomy was the operation of choice. In two cases cited complete anuria was caused by stone in the ureter; both recovered after removal of stone. Neither of the patients appeared to be sick as a result of the anuria. When bilateral calculi exist the operative method appeared best removing one stone at a time. The side showing evidence of acute trouble was operated on; if there was no apparent difference he preferred to remove the stone from the ureter on the side having the least function. Dr. Braasch had removed ureteral stones in about 126 cases by the nonoperative methods. During the same period 400 patients were operated on; about one-half the patients required operation to rid them of stone. Forty-eight cases (12 per cent.) of the 400 patients had passed stones with gravel before operation; in nine cases multiple stones were passed. The operative results were good, two deaths occurring in 400 cases, only one of which was directly due to the operation. The study of this series of 400 patients operated on for ureteral stone and the 125 patients treated by Braasch led him to conclude that before instituting any method of treatment for the removal of stones from the ureter it was well to bear in mind that a large percentage of such stones passed voluntarily; in the early cases, therefore, it was best to delay treatment.

Uretero-Ureteral Anastomosis.—Dr. REUBEN PETERSON of Ann Arbor, presented this communication, of which the following were the conclusions: "(1) No case of uretero-ureteral anastomosi can be classed as cured or successful until so proved by the most modern exploration of the repaired duct and the corresponding kidney. (2) A study of the literature of ureteral anastomosis by various methods shows that anastomosis by the end-to-end, end-in-end and end-in-side methods was a perfectly feasible procedure. (3) Not only can the duct be made patent with little or no stricture, but a functionating kidney and ureter can result. (4) In skilled hands the primary mortality due to any one of the three methods should be very small. (5) Leakage after uretero-ureteral anastomosis probably in the large majority of cases means failure, since it leads usually to stricture, hydroureter and hydronephrosis. (6) Judged from this standpoint the invagination methods are preferable to the transverse end-to-end method, since they are followed by fewer cases of leakage. (7) The end-in-end method of anastomosis was the operation of choice, since it was extremely simple and sacrifices the minimum amount of the ureter. (8) As claimed by Alksne, from an experimental study of the different methods of uretero-ureteral anastomosis there is evidence to show that every uretero-ureteral anastomosis, no matter how perfect may be the surgical result, will be followed by a slight degree at least of hydroureter and hydronephrosis. (9) Although such a claim is borne out by the findings in the case reported, it needs to be confirmed by careful examination of other operated cases."

Sarcoma of the Stomach, With Report of a Case and an Analysis of 86 Cases Operated On.—Dr. WILLIAM D. HAGGARD of Nashville, Tenn., said primary gastric sarcoma was one of the rarest surgical diseases. There was but one example of sarcoma of the stomach in 8,400 specimens of sarcoma in the Berlin Pathological Institute. Sarcoma was present in only four of the 921 cases of gastric cancer operatively and pathologically studied by Smithies. Sarcoma of the stomach might occur at any age in life. The youngest case was that of Finlayson, a boy of three and a half years, and it had been known to occur in a man of eighty-five. Although sarcoma had been thought to be a disease of young life, it more frequently involved the stomach after the fortieth year of life. Of the 25 cases analyzed, the age was given in 20. The youngest was a boy aged 16, the oldest a woman aged 66. Sarcoma was said to metastasize in 40 per cent. of the cases. In this regard it was not nearly so malignant as cancer. It was prone to metastasize in the skin. A certain diagnosis of sarcoma of the stomach before operation was practically impossible. Only an operative diagnosis was possible. Hemorrhage from the stomach and blood in the stools was a frequent occurrence, especially in the round cell variety, although in sarcoma it was not as frequent as in cancer. Early exploration should be invoked.

A Successful Posterior Gastroenterostomy 76 Hours Following a Rammstedt Operation Which Failed to Relieve the Obstruction.—Dr. FRANK D. SMYTHE of Memphis, Tenn., submitted for consideration the advisability of resorting to posterior gastroenterostomy as a last resort in cases having recently undergone a Rammstedt operation resulting in failure to relieve the obstruction. He was justified in assuming that the operation had failed where symptoms persisted for two or three days after the operation had been done. He did not know what per cent. of patients dying following a Rammstedt operation was due directly to failure of relieving the obstruction, but he did know that whatever the percentage might be they should be given the benefits offered by a gastroenterostomy, and the surgeon adopting that policy would be agreeably surprised at the results of his efforts, and that an otherwise hopeless case would be saved.

Ileostomy for Postoperative Obstruction Following Appendectomy.—Dr. EDWARD P. RICHARDSON of Boston, Mass., said that in considering the place of enterostomy in the treatment oi intestinal obstruction, a distinction should be made between obstruction occurring spontaneously or late after operation and that occurring early after operation during the period of convalescence. In the latter class of cases obstruction was most frequently due to recent plastic or partly organized adhesions, which represented temporary rather than permanent causes of obstruction. Seven cases of obstruction occurring during convalescence from appendicitis were reported, in five of which ileostomy was done for obstruction apparently mechanical in nature. In these five cases, four of whom were children, recovery with spontaneous closure of the fistula occurred, the patients remaining well for from one to eight years. These re-

sults suggested that ileostomy was a more favorable method of treatment in obstruction by recent adhesions than in other types of obstruction. Good results depended on operation being undertaken early, and it was far better to operate on an occasional case unnecessarily than to postpone operation until the later stages of obstruction had developed.

Intussusception Resulting from Benign Tumor of the Intestine: Report of Three Cases.—Dr. A. MURAT WILLIS of Richmond, Va., said that in approximately 25,000 operations at the Boston City Hospital, adenoma of the small intestine was encountered only once, and was not associated with intussusception. Operations for intussusception in young children were often grave emergencies, and the surgeon was chiefly concerned in making a decision between simple reduction and excision of the invaginated gut. It was reasonable to assume that many specimens of intestine removed at operation for intussusception, if carefully studied, would show a tumor or the remains of a tumor spontaneously destroyed by the pressure necrosis of the accompanying hyperperistalsis and the associated interference with its vascular supply. More and better study of a larger number of intussusception specimens was necessary to determine the relationship between tumor and invagiantion.

Perforation of the Gastrointestinal Tract.—Dr. CHARLES N. COWDEN of Nashville, Tenn., said in every case of perforation, no matter what the condition of the patient, there was an absolute indication for immediate operation. If the symptoms pointed rather definitely to perforation, but the diagnosis was in some doubt, exploration was safer than delay. Closing the opening was a *sine qua non* to success in any of our operative measures. Shock was no contraindication to operation. The operation should be as expeditious as possible, only what was necessary being done, and artistic ideals should be left to less urgent cases.

Surgical Drainage from a Biological Standpoint.—Dr. J. SHELTON HORSLEY of Richmond, Va., stated that drainage from the abdominal cavity was practically always uphill, and yet it was successful because the drainage material not only relieved the pressure, but provoked the outpouring of large quantities of lymph in an effort to extrude the drainage material, and this serum carried along with it products of bacterial infection that might otherwise be absorbed. In solid soft tissue, as in the thigh, the lymph supply was not so abundant and consequently gravity drainage must be used. In the abdomen the supply of lymph was so abundant and its pouring out so constant along the drainage tract that it made little difference whether the drainage tube was pointed up or down, so long as it was of sufficient size and of the proper kind of material to provoke the outpouring of serum. Drainage should be instituted after every radical operation for cancer of the breast or neck, as it tended to prevent the absorption of cancer cells that might be left in the wound. Drainage of infected epithelial lined hollow viscera carried off the inflammatory products, afforded physiologic rest, and also produced a reversal of the circulation of the local lymphatics, that would prevent the absorption of much of the septic products. Drainage material should be selected with a view to inducing a reversed flow of lymph to carry away the liquid products of the wound, and also with a view to injuring the wound as little as possible. Ideal drainage material had not been found, but empirically combinations of gauze and rubber tissue had been worked out that were fairly satisfactory.

President's Address: Embryology and Surgery.—Dr. JAMES E. THOMPSON of Galveston, Tex., opened his address with a reminiscent sketch of the Louisville meeting in 1892, and a eulogy on the high character of the scientific work presented before the society and its value from an educational standpoint. Some embryological aspects of surgical pathology were then considered. Familiarity with common anomalies ought to be the ordinary stock in trade of every surgeon, and the broad educational value of a minute acquaintance with all errors of development could not be overestimated. Comparative embryology must not be neglected because many anomalies, especially those affecting the genitourinary organs and the rectum, could only be explained by studying them side by side with adult conditions in the lower vertebrates. A detailed description was given of the rotation of the midgut and its effect on the final disposition of the jejunum, ileum and the part of colon involved. Nonrotation and arrested rotation were illustrated by examples taken from the human body and from the lower vertebrates. In this connection misplacements of the vermiform appendix and abnormalities of the colon were discussed; also volvulus of the small intestine and retroperitoneal hernia into the fossa duodenojejunalis. The latter part of the address dealt with the origin of some cysts of the neck of branchiogenetic origin. A type of cyst lying in the upper part of the neck under cover of the parotid gland and the lower jaw was described carefully. The cysts had thin walls lined sometimes by tessellated epithelium and the contents were thin mucus. They occupied a definite position and had the following boundaries: Above, the base of the skull represented by the under surface of the petrous portion of the temporal; behind, the anterior border of the mastoid and styloid processes and the bodies of the upper cervical vertebrae; externally, the parotid gland and the medial surface of the ramus of inferior maxilla. They often communicated by a narrow neck with a similar cyst in the submaxillary region, and occasionally by means of the submaxillary cyst with a true ranula in the floor of the mouth. Numerous examples of such cysts were displayed, which supported the view that ranula was probably derived from the cervical sinus which had been carried from its original cervical position into the tongue by migration of muscles belonging to the segments of the primitive embryo supplied by the hypoglossus nerve.

My Observation of the Carrel-Dakin Treatment of Infected Wounds.—Dr. E. DUNBAR NEWELL of Chattanooga, Tenn., said that it was almost universally observed in the hospitals of the American Expeditionary Force that patients whose infected wounds had been properly treated by the Carrel-Dakin method suffered less pain, had less systemic infection, were more alert and cheerful, had a more rapid convalescence, and the wounds closed far earlier and with less deformity and less morbidity than in those patients whose infected wounds were treated by other methods. It was his firm opinion that in the Carrel-Dakin method of treating infected wounds, whether civil wounds or war wounds, we had the most valuable contribution to the treatment of infected wounds since the days of Lister.

The Results and Feasibility of Treating Lymphangiomata.—Dr. FRANCIS REDER of St. Louis said in his service of ten years at the City Hospital he had had occasion to observe only four cases. The scarcity of patients affected with a true lypmhangiomatous growth seeking hospital care must be ascribed to some extent to the fact that these tumors seldom threatened life; that they did not cause pain, nor did they cause the individual to feel sick. Lymphangiomas were usually congenital, and the thought of a mother taking her baby to a hospital for a small tumor mass somewhere on its body which did not cause pain was rather a remote one. When confronted with a tumor of any sort the thought uppermost in the surgeon's mind was whether or not the growth was a suitable one for excision. Extirpation was the radical and most satisfactory measure in the treatment of lymphangioma, if the operation could be safely done. In that form of nevoid lymphangioma affecting the tongue, causing marked enlargement of that organ and forcing it to protrude from the mouth, partial removal by a cuneiform excision was the only measure, even at the risk of causing progressive inflammation or lymph fistulæ. A similar procedure, but with greater risk, could be undertaken when the disease had attacked the lip. In comparing the results obtained in the lymphangiomas with those of the hemangiomas it must be said that they had been somewhat disappointing. This must be attributed to the difference of the fluids in these tumors. So far eight cases had been injected with boiling water. The reaction following the injection seemed unusually severe when compared with the reaction following the injection of a hemangioma. For twenty-four hours the patient gave evidence of feeling sick and usually registered a temperature of 100° to 101° with a pulse of 100 to 110. When the reaction had passed off, which was

generally after the third day, the feeling of euphoria returned. The increase in the size of the tumor after the injection, although considerable, bore a minor ratio to the increase seen in hemangiomas after injection. Inflammatory processes seemed active and prolonged, the skin giving evidence of the severity by a marked reddish discoloration. Retrogression seemed very slow. It required from four to six months to show that the tumor had decreased in size. In the case of a baby with the left foot about four times its normal size, it required two years for the foot to attain the size to be fitted with a shoe. Subsequent injections were almost impossible to be given, if the initial injection had been a thorough one. The tumor mass was so hard that no hot water could be forced into it. Of the eight cases injected with boiling water all had been benefited, but in none had the tumor entirely disappeared.

Some Plastic Operations on the Rectum.—Dr. HARVEY B. STONE of Baltimore stated that in certain special type of structure of the rectum, an application of the principles of the Heineke-Mikulicz pyloroplasty was helpful. These strictures were of the diaphragm type; that is, firm, with small lumen, but narrow and annular in their involvement of the long axis of the bowel. The stricture was incised in the posterior midline down to its space, and the superior and inferior edges of the incision were sutured to each other, so that the line of repair ran transverse to the long axis of the bowel. After having employed this measure several times, he found that it had already been described by Dr. Arthur Dean Bevan in Chicago Clinics, 1917. In tubular strictures of the rectum, occurring in the lower four inches of the bowel in multiparous women, the utilization of part of the voluminous vaginal mucosa as a transplant into the rectum had been tried. This had been done only when long continued dilatations had failed to give relief, and where the Wassermann test had been for a long time negative. The posterior vaginal wall was incised longitudinally in the midline, exposing the strictured rectum from in front. Some of the scar tissue about the rectum was dissected away, and then it was incised longitudinally in the anterior midline. The edges of the vaginal incision were sutured to the corresponding edges of the rectal mucosa, thus forming a rectovaginal fistula, then on bearing the fistula was amputated and the stump of proximal bowel sutured to the anal skin as in Whitehead repair. The perineal incision was also closed. The advantages of this operation were direct closure of the urethral orifice, the complete removal of the fistulous area of rectum, the interposition of perineal structures between rectum and urethra, and the temporary diversion of the urine. It had proved very successful in practice.

Autogenous Bone Grafting for Repair in Fractures of Long Bones.—Dr. FRANK MARTIN of Baltimore said in removing and implanting grafts many factors could easily enter which would weaken or destroy the viability of the graft, such as chemical contact, drying or burning graft with a too hot saw, or other mechanical injury, and to achieve the best results these factors must be guarded against. The more quickly and surely the graft was implanted and definitely fixed, the more promptly was nourishment assured. Intimate apposition, which would assure early adhesion between the wound edges and the transplant, would more certainly serve the function of supplying as quickly as possible nutrition to the graft. The most important contributing factor to failure, next to improper technique, was imperfect hemostasis, as it prevented intimate adhesion of the graft with the wound edges,.and invited infection. The chief factors for successful bone grafting were perfect aseptic technique, avoidance of mechanical injury or trauma to the graft, scrupulous avoidance of traumatizing tissues, definite and firm fixation of the graft, allow a long interval to elapse after complete healing of the wound. Grafts would not remain viable where there was infection. There should be perfect hemostasis.

Oxycephaly; Report of Two Cases With Decompression Operation in One.—Dr. STEPHEN H. WATTS of Charlottesville, Va., said it was only in recent years that operative measures had been undertaken with the object of combating the symptoms of increased intracranial pressure, especially the threatened blindness. Since most observers thought that this increased pressure was due to the disproportionate growth of the brain and skull, decompression seemed to be the operation of choice; moreover, it had the advantage of simplicity and relative safety. It should be done early, for in cases with irreparable optic atrophy and no other pressure symptoms, operation was not indicated. The results of this operation in the small number of cases in which it had been done were distinctly encouraging, in spite of the fact that the optic atrophy was rather advanced in most instances. In 1916 Sharpe reported four cases of oxycephaly in which he had done subtemporal decompression, unilateral in one, bilateral in three. The three cases in which the bilateral operation was done were followed and found to be greatly improved; the other one could not be traced. The case here reported, in which the author did a bilateral subtemporal decompression, was seen about two years after this operation. The parents stated that his general condition was much better, and that he seemed to see better, as he stumbled much less in walking. He could count fingers at three feet, which he could not do before operation. Examination of the eye ground, however, showed practically no change, there being a marked optic atrophy in both eyes. An interesting feature of the case at operation was that the bulging of the brain was so marked that the temporal fascia could not be at all approximated on either side, therefore the defects were covered by transplanted patches of fascia lata. Another point of interest, Dr. Watts said, was the ossification of the tissues over the region of the decompression, this bone showing the same digital impression as the rest of the skull.

An Efficient Treatment for Carbuncle.—Dr. A. C. SCOTT of Temple Tex., said that by strong traction the mass was lifted out of its bed while the cautery swept back and forth between it and the cellular tissue below or skimmed along the fascia covering the muscle beneath or penetrating muscle, if necessary, until the entire mass was free. Should any vessels spray freely or fail to close when the dark red cautery was held in contact with them a few seconds, they should be at once seized with mouse tooth hemostats and later ligated, if necessary. A touch of the cautery for a few seconds to the end of the hemostat while in place would often render ligation unnecessary. Any doubtful places beneath the remaining skin margins should be explored by the cautery tip. If the emission of steam was noted it should be applied until the cavity was apparently dry. Such a wound was now sterile and might be handled as any sterile burn. Dakin's solution might be used to advantage to keep the wound sterile and hasten the preparation for skin grafting. As soon as all burned tissue had been cleared away, perforated skin grafts sufficient to cover the granular surface soon completed the cure. The conclusions reached by him were based on the observation of 32 cases of carbuncle treated by the application of the cautery. Compared with former experiences, the period of convalescence appeared to be conservatively 50 per cent. less than by the old methods of treatment.

Gas Gangrene in Typhoid Fever Following Hypodermic Infusion.—Weinberg and Francon saw gas gangrene develop in both thighs of a typhoid patient in the sites of infusion punctures. The substances infused were saline infusion and solutions of sparteine and adrenalin. The infection was ushered in by a drop in temperature and the patient succumbed three days later. Eberth's bacillus was found in the blood and the perfringens in the sloughs of the gangrenous process. But three similar cases are on record and of these two were reported by Brieger and Ehrlich in 1882. The rationale excluded local inoculation although the punctures were of course responsible for the accident. There is little doubt from what we know of the perfringens that it gained the blood from the intestine passing through ulcerated Peyer's patches. There was an attempt to save the patient by injecting 200 c.c. of antigangrenous serum and the specific effects upon the process were most striking, edema and crepitus promptly disappearing. Death was ascribed to the symbiosis of the typhoid and perfringens bacilli in the blood and would doubtless have occurred in the absence of the gangrene.—*La Presse Médicale.*

Therapeutic Hints.

Dorsey's Magnesia Solution.—Samuel E. Earp, of Indianapolis, states that the improved formula of Dorsey's Solution is superior to Epsom, Rochelle, or Glauber's salts, having none of the objections of these salines and possessing many advantages over them. The Indianapolis City Hospital used 250 gallons of this solution last year. All the other hospitals of the city keep it as a stock solution, as do likewise the pharmacists. For a small quantity the following is the formula, as it has been improved:

℞ Sulphate of magnesia, 1 pound,
Granulated sugar, 6 ounces,
Aromatic sulphuric acid, 1 fluid ounce,
Citric acid, 90 grains,
Water, 2 pints.

Dissolve magnesia sulphate and sugar in one pint of hot water and add acids, and the water q.s. to make two pints and filter.

This solution is more pleasing to the palate than most solutions of like character; the astringency and stimulation to the mucous membrane by the acid gives it an advantage; there is greater certainty to evacuation; if given in proper doses, suitable to the patient's condition, there need be no continuous watery stools.—*Western Medical Times.*

Injection Method of Treating Goiter.—Joseph Eastman Sheehan and William H. Newcomb have continued the investigations reported by the former two years ago (MEDICAL RECORD, October 6, 1917), with the injection method of treating goiter. Eighty cases of all forms of goiter were injected at regular intervals for the past two years, with a mixture of equal parts of phenol (carbolic acid), tincture of iodine, and glycerin. The eighty cases represented more than five hundred injections. There were no untoward results from injecting the phenol preparations.

The object of the injections is to produce an inflammation, which eventually causes a fibrosis in the gland and the obliteration of that part of the gland injected. The injections are particularly suitable in the ordinary parenchymatous goiters of young women. Of 55 patients of this type injected, 76.4 per cent. were cured. It relieves the thyrotoxicosis, as in exophthalmic goiter, but the relief is only temporary. In 14 toxic cases, relief was given in 80 per cent. It is of no avail in the cystic or colloid form, and if persisted in, in this type, may cause a sudden enlargement of the gland, seriously interfering with respiration. Sheehan and Newcomb inject all goiters to be operated on. The solution used consists of five drops of equal parts of tincture of iodine, chemically pure phenol and glycerin, and this is injected into the most prominent part of the gland. It is never safe to inject more than 12 drops.—*Journal of the American Medical Association.*

Pepsin.—In a discussion of points in the pharmacology of certain drugs used for stomach effects, Bastedo makes the following observations regarding pepsin: By the U. S. Pharmacopœia test, with 1 in 3,000 hydrochloric acid at 125.6° F. (52° C.), pepsin is required to digest 3,000 times its own weight of coagulated egg albumen in two and one-half hours, *i.e.* 1 grain of pepsin can digest at least 6¼ ounces. A specimen has been prepared 200 times as strong as this, *i.e.* 1 grain can digest 600,000 times its weight. It is activated by hydrochloric acid above 0.5 per cent. strength (U. S. P.), 0.7 to 0.9 per cent., and by sodium chloride solution of 2.5 per cent. strength. It is not only inactivated but is destroyed by alkalies; for example, disodium phosphate in ½ per cent. strength, sodium hydroxide in 0.01 per cent. strength, and sodium bicarbonate and carbonate, magnesium carbonate and limewater, when in sufficient amounts to make a persistent alkaline reaction. In the light of this destruction one wonders how Abderhalden and Meyer were able to find active pepsin in all parts of the small intestine, and to suggest that this pepsin would taken an active part in the digestion of protein wherever the intestinal contents should become acid.

In the stomach contents, it has been found absent or below normal in every one of a thousand cases of achylia gastrica (Wiltrup). It has been found absent in 3 cases and present in only very small amounts in 16 out of 22 cases of gastric cancer and in normal or above normal amounts in 65 cases of hyperchlorhydria, 37 cases of gastric or duodenal ulcer, and 85 cases of cicatricial stenosis of the pylorus (Hernando and Alday).

It is evident then that the only possible cases for the use of pepsin in therapeutics would be those of subacidity and achylia, whether cancerous or not. Its need is doubtful, but since pepsin digests protein only when this has been changed to acid albumin, if used at all it should be accompanied by a sufficient quantity of hydrochloric acid.

Pepsin preparations regularly have a milk-coagulating power. Whether this is due to admixture of rennin or because pepsin and rennin are one and the same enzyme is a still unsettled question among physiological chemists.—*American Journal of the Medical Sciences.*

Enuresis Treated by Dietetic and Hygienic Measures.—Considering enuresis an expression of neuromuscular fatigue, in which too much or too vigorous exercise, too little sleep, mental strain, and improper diet play a part, Grover advocates the treatment of the symptom by hygienic and dietetic measures, to the exclusion of drugs, operative measures, and mechanical means. The diet includes milk, butter, eggs, meat, fish, bread, cooked cereals, macaroni, vegetables, oranges, stewed fruits, and simple unsweetened desserts. Food between meals is forbidden, and meat, vegetables, and eggs are not to be taken at night. Soups, coffee, tea, cocoa, sweet, salty and highly seasoned food, sweets, pastry, cake, jellies and jams are on the list of forbidden articles. No fluids are to be taken after 4 P.M. The hours for urination are regulated. At night the hours are 7 P.M., 10 P.M., and 6 A.M., except for children whose bladders cannot hold more than from two to three ounces, in which case urination is permitted at 2 A.M. Those who require daytime regulation are allowed to urinate at intervals of from twenty minutes to three hours. The interval is gradually lengthened until proper habits are formed. It is not to be overlooked that the habit may tend to persist, even after all the factors enumerated have been corrected.—*British Journal of Children's Diseases.*

TREATMENT AND MANAGEMENT OF THE NEURASTHENIC INDIVIDUAL.*

BY C. F. NEU. M.D.,

INDIANAPOLIS, IND.

BEFORE attempting to outline a course of treatment for this condition, it might be well to indicate somewhat briefly just what is intended to be included under this term, and to direct attention to those factors and influences that are believed to exercise some causative relationship toward the generation of the symptom-complex that is usually found, since these would be perhaps the best indications to guide one in the selection of measures and means to be utilized.

The term is frequently applied to a conglomerate group of more or less unrelated conditions, often made to include what unquestionably are mild forms of definite psychotic states, of hysterical conditions, and also of the results of gross organic brain or nerve lesions. The term neurasthenia should be restricted to an enfeeblement or fatigue neurosis, a primary fatigue neurosis, its cardinal characteristics being an inordinate sense of physical or mental fatigue, or both, a difficulty in concentration, of attention and application to work, a sense of pressure in the head, and irritability of the spine, various paresthesias, and more or less disturbance of function of the various visceral organs, all being more or less closely related to psychogenic factors. Clifford Allbutt, in his "System of Medicine," applies the term to what he calls a characteristic series of symptoms recurring with fair uniformity. Burr states that "in neurasthenia we are dealing with a psychic disease, generally called a neurosis," which perhaps soothes the fears of the patient or the family, who fear and dread a so-called mental breakdown or mental disease; but physicians should not be misled by this fear to a nonrecognition of the fact that the most important and essential symptom of the disease is of a purely psychic character. The so-called psychasthenic states especially, which are really a phase of and should be included under the term, belong to the broad borderland between mental health and disease, and are distinguished from many forms of psychoses only by the slighter degree of their manifestations. Jelliffe writes that "in the normal individual, even with the most grievous form of bodily suffering, the mind is preserved relatively intact, so that one is able to meet the trouble by the philosophy of reason and religion, but in the neurosis, neurasthenia, the mind itself is the seat of the pathogenic disturbance, and the individual realizes that the conflicts taking place in his own mind are more or less at the root of the trouble." This is clearly indicated by the frequency with which one hears such patients repeat the cry, "If they could only forget or escape from their own thoughts how much more bearable the condition would be."

Causes.—No cause is so often assigned as overwork, but it is usually found that insufficient time for rest, insufficient sleep, days spent in feverish activity, evenings and Sundays in working out new plans, have all been factors in bringing about the final breakdown.

Conditions of great exhaustion are especially liable to follow certain severe physical diseases such as typhoid fever and influenza, and this suggests that probably certain toxines are of some importance. But since the majority of individuals who suffer from such diseases do not acquire the neurasthenic state, it is evident that there must be other underlying factors responsible. Moreover, similar conditions are found in nontoxic states, such as profound hemorrhages and painful conditions, with loss of sleep; but even here it may be that, in the modification of chemical changes resulting therefrom, toxic substances may be formed, and play their part.

Many neurasthenics connect their conditions with sexual irregularities or disturbances of the sexual functions, especially masturbation or nocturnal emissions, but since the great majority, particularly males, have performed it more or less at some time, it should not be rated very high as a causative factor, not even where it has been carried out to an unreasonable degree. It is much more probable that these are more the manifestation of an underlying irritable nervous or psychopathic predisposition or the symptom of a graver incipient, psychic disorder. Furthermore, as a rule, it will be found that the harm resulting therefrom is not due to any effect upon the physical condition, but to the mental conflicts that arise in the moral and spiritual life. This is further exaggerated by the abominable literature spread broadcast, dealing with the subject, and by the medical charlatans found everywhere, preying upon the suggestible victim; both of these only too easily form an indelible impression upon the mind, and are of great influence, since the resulting fear instilled is a constant source of irritation and unrest.

To what extent measures adopted to prevent conception may be regarded as a causative factor it is difficult to say. It seems probable that the strain on the attention, and the effect otherwise, both

*Read at the twentieth annual session of the Ohio Valley Medical Association held at Evansville, Ind., November 11 and 12, 1919.

physically and emotionally, may disagree with many, and give rise to nervous troubles. In all of these sexual conflicts it seems probable that the exhaustion is more the result of the mental struggles in the moral conflict than in the physical acts themselves, and the extra exertion necessary to furnish the excitation that comes from without.

The excessive use of such drugs as alcohol, opiates, coffee, and so forth, is also believed to have a causative relationship in some cases, but caution must be observed in determining whether the excessive use is not a manifestation rather than a cause, for it is well known that the majority of these individuals are particularly susceptible to the action of such drugs.

Trauma is one of the most important causes, particularly where the question of compensation comes into consideration. The idea that all the compensation possible to obtain is due the injured, and the mental anxiety that arises because of the uncertainty of the outcome, together with the various discussions and suggestions heard during the examinations and consultations, often do more to initiate and engender the development of the neurasthenic state than the injury itself.

It is a well recognizable fact that the neurasthenic breakdown appears more readily when intense emotional disturbances are combined with unusual or excessive demands upon the physical powers.

In the so-called constitutional neurasthenic or psychopathic constitution, general nervousness rests upon a congenital predisposition, but even in these the hereditary tendencies are often looked upon as childish misdeeds or naughtiness. In children of this makeup, furthermore, improper or perverted education and training are often among the most serious injurious influences, in that they tend to intensify or exaggerate innate potentialities. Such factors as the unnatural forcing of some manifest talent, the stern, misunderstood rebuke of some nervous condition of fear or anxiety, excessive pampering or yielding to selfish desires and whims, the habit of more or less constantly directing the attention of not only the child but also of its environment to the manifestations of nervous disorder in the child, these interfering with and preventing the employment of conscious effort and energy to overcome them, all play a part in laying the foundation upon which future trouble develops; so also do the improper demands made by improperly chosen and directed school work upon both physical and mental powers of the child. Nature usually attempts to protect such children by creating a tendency to inattentiveness where prolonged and uninterrupted concentration would prove harmful. This inattentiveness renders the task more difficult for the nervous child, and in order to overcome the difficulty it is driven to greater struggle in the effort to concentrate, thus causing fatigue sensations, and this combined with the fear of criticism, censure, or failure, often brings about the ultimate collapse. This collapse is frequently seen following the extra effort and anxiety necessitated when preparing for examinations or undertaking new and difficult obligations. Children of this constitutional makeup, as well as adults, are usually endowed with an increased or intensified sensitiveness, hence are more strongly stimulated by ordinary impressions than the normal child, thus tending to intensify further their excitability and restlessness. Their imaginative faculties, already overactive, are further incited and intensified by the character of fairy tales told them or given them to read. The same may be said of the habit many parents have in taking them to improper theaters or moving picture shows to quiet them or satisfy their desires or demands for entertainment. All such activities tend to create unhealthy thoughts, feelings, emotions and ideas of life in its reality of everyday experience. In adults of this constitutional makeup emotional excitement or strain plays a prominent, if not the chief, rôle in bringing about the ultimate breakdown. It is estimated that nearly 80 per cent. of all neurasthenia develops upon an inherited predisposition.

In summing up the probable causes of neurasthenia, it is perhaps correctly stated by one authority who says that "the theory of neurasthenia will not consist primarily in vascular or nutritive hypoplasia, nor in toxic states, however necessary these may be as aggravating factors, but it will prove to be a nonspecific state, one to which on sufficient disturbance, every nervous system is liable. Most frequently the malady depends upon a disposition of the nervous mechanism, a disposition often inherited, which is or implies liability or incapacity."

Symptoms.—A few words as to symptoms. It does not require very close observation to recognize that many of these are due as much to physiological functional activity, improperly carried out, as to actual loss of function, occasioned by disease. While there is not a function or organ of the body that may not be the seat of more or less disturbance, yet it is usually found that one or more special groups are predominately involved. The more common of these may be grouped under the following divisions: (1) Cerebral. (2) Spinal. (3) Cardiovascular. (3) Visceral. (5) Urogenital. (6) Traumatic. (7) General.

Biborwitz, in classifying a large number met with in a sanitarium, and consisting mostly of working people, found that about 31.6 per cent. came under the cerebral group, 48.3 per cent. the cerebrospinal, 6.2 per cent. gastrointestinal, 4.2 per cent. cardiovascular, and 9.7 per cent. traumatic.

In practically all cases an inordinate sense of fatigue, both physical and mental, is the dominating feature; the slightest exertion is soon interrupted by a disproportionate feeling of fatigue, regardless of the character of the work performed. That this is more a subjective sensation than an actual exhaustion is indicated by the fact that many of these individuals, apparently helplessly exhausted, by diversion of their attention are often capable of prolonged effort. This abnormal sense of fatiguability tends to render their attention more easily distracted, thus impairing their ability to concentrate and developing a loss of confidence in their capabilities. This inattentiveness tends to lessen the effect of the impressions made upon them by the incidents and experiences of their daily environment, and as a consequence these are readily overlooked or forgotten, thus creating the impression of an impairment or failure of memory. Upon this basis there readily develops indecision, uncer-

tainty, inconclusiveness, pessimism, emotional irritability, and depression, loss of emotional control, doubts and fears of various kinds, painful thoughts, impulsive and obsessional ideas. With such a state of mind, one must expect, and as a matter of fact, one finds a corresponding proportionate impairment of the various physical functions of the body.

In all neurasthenics, during some period of their illness, sleep is more or less impaired, in that, not only are they unable often to go to sleep, regardless of how wornout or sleepy they may feel, but when able to go to sleep readily soon awake, and then tumble restlessly about the remainder of the night, or the sleep is disturbed by exhausting or terrifying dreams. Partly as the result of insufficient rest from sleep, and partly as the result of mental distress, anxiety, and fear, such patients frequently complain of various disagreeable and distressing sensations in the head, such as numbness, pressure, constriction, emptiness, fullness, bursting, and so forth, leading to more or less aching and often definite pains. The special senses are frequently involved, especially sight and hearing, less often taste and smell. In one patient the vision soon becomes blurred, in another there is hypersensitiveness to light. In one the hearing is painfully acute so that ordinary sounds or noises become a source of distraction, while in another there is more or less constant roaring and ringing in the ears.

In the spinal type there is always more or less aching, pain, paresthesia, or localized tenderness along the spine, particularly over the cervicodorsal, lumbar, and coccygeal regions. These are particularly liable to appear in the patient with hysterical tendencies. Associated with this condition, one frequently finds various paresthetic disturbances in the extremities, such as numbness, burning, tingling, itching, and pressure pains. Tics of various kinds are frequently manifested, one of the most common and distressing assuming the character of a blepharospasm, or a facial tic.

Cardiovascular disturbances are rarely absent, and in some constitute the predominating features of the symptoms manifested. The rate of heart action is usually accelerated where a disturbance of rate occurs, but there may be a retardation. Often there are intermittency, pounding or flopping-over sensations, and sometimes definite pains assuming more or less the character of anginal attacks. These various disturbances are usually not associated with any physical evidence of organic disease, or where some degree of pathology does exist, are out of all proportion to the gross changes.

In the respiratory system, one frequently finds superficial breathing or shortness of breath, a tendency to sighing respiration, and at times symptoms resembling hay fever or an asthmatic attack.

Gastrointestinal disturbances in some form are rarely absent. Erratic appetite, gaseous fermentation with its secondary pressure effects, bloating, belching, nausea and vomiting, sour stomach, various types and degrees of pain in the epigastrium or throughout the abdominal cavity, constipation, diarrheal attacks, and mucous discharges, are some of the more common conditions complained of, while frequently there is also found a more or less general systemic toxicity from the absorption of chemical products of fermentation or decomposition of the intestinal contents. Many of these symptoms are no doubt due in part to the secretory and motor disturbances resulting from an impairment of the nerve regulation, but also in part to the peculiar anatomical makeup, since many of these patients show a marked tendency to a ptosis of one or more of the abdominal visceras.

In the urogenital sphere one often meets with an excessive secretion of a limpid, low specific gravity urine, with the accompanying frequency of micturition. In others there occur over or undersensitive sexual impulses, resulting in seminal emissions, frigidity, or other impairment of the sexual function. This probably occurs more frequently in males, and forms the predominating characteristic of the so-called sexual neurasthenic, in whom the fear of the possibility of the loss of manhood makes him one of the most difficult of this class of patients to treat.

Diagnosis.—Where one meets with an individual manifesting the neurasthenic complex, in attempting to arrive at a diagnosis it is most essential to determine whether or not there is present some incipient or underlying gross physical disease. Among the more common possibilities may be mentioned tuberculosis, syphilis, arteriosclerosis, chronic renal disease, hyperthyroidism in its various phases, local infection, drug addiction, peripheral points of irritation such as refractive errors, hysteria, or incipient psychoses.

Treatment.—It has been well stated by one authority that whoever cannot rid himself of the prejudices in regard to the nervous person, who has not the patience to listen to his complaints in so far as this is necessary, who from the first does not make it the aim to educate systematically the patient toward health and to combat autosuggestion, had better forego the attempt to treat nervous diseases; and this is particularly true of the neurasthenic state. Another writer has the following to say of neurasthenia: "There is hardly any malady that receives so little understanding or even common sympathy, its unreality being assumed even by most physicians to contain something of a farce, to be a craving for sympathy, to be more under the control than the patient is willing to admit; or the patient could do better if the effort would only be made, the result of all of which is that many medical men treat it lightly, and fail to look upon it as a disease, and this attitude often serves to intensify or exaggerate the underlying anxiety or suffering of the patient.

It is generally recognized that one of the first essentials in the treatment of the neurasthenic is for the physician to win the confidence of the patient, hence it has frequently been stated that the physician who contemplates treating these patients should undergo preparatory treatment first. Without that confidence a physician will not be able to reach the fundamental sources or underlying causes, since most of these patients feel that their condition is not understood, and fail to express openly fears and thoughts that are fundamentally responsible for much of their distress, and this often leads them to direct attention to other features in order to avoid having them revealed.

On the part of the physician, a thorough, detailed

examination, during which all relevant data are noted, a proper diagnosis made, a deliberate plan of procedure faithfully and pertinaciously carried out, combined with the fullest possible cooperation of the patient, is essential. To be avoided are such conditions as the following: A discussion of the patient's symptoms with others, arguments over conditions previously considered, inconsistent methods and frequent changes in therapeutic procedures, and similar activities.

So far as the patient is concerned, in the acute condition, absolute rest, both physical and mental, is necessary, so far as it is possible to obtain this, and under conditions to avoid what some patients call a rusty sluggishness. Just how to bring this about is almost always a difficult problem, and can be solved only by a careful study of the makeup and personality of the individual patient. As a rule, this cannot be obtained under the conditions and amid the environment in which the neurasthenic state develops, and a removal from this environment is often necessary, or separation from the family and from the petty annoyances of everyday life; in other words, more or less complete isolation, a new environment being nearly always more favorable for the physician to secure more easily mental and moral control of the patient, thus enabling him the more readily to infuse into the patient not only confidence in the physician but also confidence in his own physical and mental capabilities. It has been well said that a healthy physical, intellectual and moral environment is an essential factor, not only in the prevention but also in the cure of psychoses and neuroses, because it tends to strengthen and develop the body and mind, the deliberation, judgment, and the higher controlling functions of the brain. The advisability of isolation combined with nutritional building up was emphasized years ago by Playfair and Weir Mitchell, who formulated the triad of basic principles in the treatment of these patients, namely, isolation, full feeding, and massage.

Sometimes, however, isolation becomes disagreeable and unbearable, especially when conditions are uncongenial and unattractive. The solitude may become almost intolerable. Business and family worries, contact with outside incidents which tend to excite or stimulate the imaginative faculties must be eliminated. A congenial, companionable, commonsense nurse, tactful, determined, yet sympathetic, a combination unfortunately not often met with, can do more by her ingenuity and thoughtfulness to bridge over a crisis than any other one factor. Entertaining conversation, interesting light reading, both by the nurse and by the patient, will often serve to dispel distressing, gloomy thoughts and drive away dreaded fears.

The regulation of the diet is also an important factor, since the majority of these patients are not only undernourished, but also suffer from more or less digestive disturbances. The diet should be nutritious, easily digested, readily assimilated, and given in more or less graded quantities. Stimulants, such as wines, liquors, and strong tea and coffee, should be avoided. The chief indication is to force the feeding so far as it can be assimilated. Meat should be used in moderate quantities—once a day is, as a rule, quite sufficient. In addition to the ordinary rations at regular meal time, milk, plain or modified in various combinations with cream, rice, cocoa, or soups, up to four to five pints daily is often beneficial. This is often best accomplished by giving a certain amount at regular intervals, say three to five ounces every three hours.

Massage, especially in the weakly, should take the place of more active muscular exercise. This to be effective must be selective, and the person giving it should be endowed with an agreeable manner, have a delicate touch, and possess the technical knowledge of its uses and the manner of its being given. The individual who assumes to take up massage also should possess adequate muscular strength, sufficient endurance, a cheerful disposition, and a wholesome temper.

After the acute manifestations have subsided, and the patient's condition warrants it, more active measures must be considered. Graduated methodical exercises incorporating constructive ideas and activities are to be preferred, since those that are aimless and objectiveless, such as ordinary gymnastics, aimless walking, and so forth, are often worse than useless. In selecting any particular line of activity, either physical or mental, one must be guided by the inherent likes and dislikes of each patient. Vocational therapy should be the goal sought for. Gentle hill climbing, boat sailing, riding, gardening, carpentering, basket weaving, photography, painting, music, nature study are a few of the activities that are available. Just here it might be well to emphasize one point wherein there is an almost universal tendency to err. We are all more or less inclined to lose sight of the fact that these patients lack incentive, lack initiative, lack confidence in their capabilities, lack the ability to arrive at a definite decision or conclusion, lack the judgment necessary to determine to what extent or how vigorously to carry on the activities; hence, when such responsibilities are placed upon their shoulders, the worry and anxiety induced nullify any benefit that might otherwise accrue. The best results are obtained when there is someone who can assume these responsibilities, and instead of telling such patients to do these things of their own accord, will take the initiative, work along with the patients, supervising, directing, and regulating their activities, whatever they may be. The regulated control of the patients' muscular activities tends to develop a similar control of the mental and emotional faculties, gives them encouragement, instills into them confidence, and infuses them with hope, all of which must be generated as the patient struggles up the road to convalescence and recovery.

Hydrotherapy and electrotherapy also have a place as therapeutic measures, but must be selective. Given indiscriminately, they usually do much more harm than good, since when no benefit is derived they only serve to impress more deeply upon the mind of the patient the hopelessness of the condition. Wet sheets, baths of various kinds, hot and cold packs, showers, douches, and sponges, all have their place. As a rule these patients bear cold water badly, hence when these applications are desired it is advisable to begin with warm water, gradually lowering the temperature by the addition of cold water to the point desired. The results of

electricity depend to a great extent upon the tact, confidence, and experience in its use. The faradic bath, lasting from twenty to thirty minutes, sufficiently strong to produce tingling but no muscular contractions, at times soothes nervous irritability, lessens muscular weakness and fatigue-sensations by bringing about muscular relaxation and lessening of so-called nervous tension, improves the appetite and general tone, and creates a feeling of sleepiness. In other cases the galvanic current applied along the course of irritable nerves lessens their exaggerated functional activity, such as hypersensitiveness, excessive sweating, and so forth. In other cases the high frequency, the autocondensation, and other forms prove beneficial.

Drug administration must be determined mostly by the character and intensity of the individual disturbances manifested by the different organs of the body. There is probably not a drug in the U. S. Pharmacopœia, not to mention many proprietary remedies, that has not at some time or other been administered.

Bromides are frequently required to lessen the nervous restlessness and so-called tension which is almost constantly complained of. Also in the so-called cerebral group where patients complain of vague sensations of fullness or emptiness, vertigo, subjective feelings of failing memory, of confusion, and so forth, the bromides, either alone or combined with valerian or some of its modifications as valyl, bornyval, and so forth, are beneficial. It is generally recommended that the bromides be given in small doses, and over short periods of time, but one often finds that relatively large doses are required to produce the desired muscular relaxation, and lessening of the nervous excitability. Their action is often assisted by dissolving the salt in hydrobromic acid and combining with quinine or bismuth where indications for these are found. Where there is evidence of considerable vasomotor instability, the addition of ergot often serves to ameliorate or dispel disturbances dependent upon these conditions.

Strychnine, which is so frequently given to those patients complaining of weakness and exhaustion, often does more harm than good, for the reason that the great majority are already overstimulated and require soothing remedies instead. It is beneficial in those cases where there is more or less atonia with mental and muscular relaxation.

Sleeplessness is, as a rule, one of the most difficult disturbances to control. So far as possible, sleep should be secured by such measures as baths, massage, exercises, or nourishment. Where hypnotics are required, it is found that veronal, trional, sulphonal, and similar remedies are serviceable. At times it becomes necessary to resort to more active remedies, such as paraldehyde, chloral, and even morphine, but the latter should be used only as the last resort, since, as is well known, this drug affects unfavorably many of the secretions, and besides there is always the grave danger of inculcating the drug habit.

The gastrointestinal disturbances nearly always require remedies to relieve the distress and to regulate the impaired functional activity. In the selection of remedies to be used one must be guided not only by local but also by general conditions, as well as the reaction of the patient to the particular remedy used.

The question of climate, when a change of environment and climate is advised, is also of importance. Generally speaking, a dry, sunny, mountain country has been found to be the most beneficial, especially in the summer time. Where a change to a higher altitude is made, it should be taken up gradually until an altitude of about 3000 feet is reached, this, as a rule, being the most satisfactory. The action of sea air is said to be uncertain, and while at times it proves beneficial, it is often found to intensify the restlessness, tension, and sleeplessness. In the later stages, when good progress has been made on the road to recovery, sea-bathing at times is very beneficial. Winds are said to be harmful, as a rule, tending to intensify existing disturbances. From the frequency with which traveling and sea voyages are advised, it requires a word of caution to consider the other features necessary before deciding upon them as a therapeutic measure. Much more depends upon the companion, the food, and the weather than upon the journey itself, but where the companion is congenial and entertaining, the food attractive and tasty, and the weather pleasant, benefit must accrue therefrom, but such a combination is rather a matter of chance than the result of human ingenuity.

Psychotherapy, as a rule, can best be carried out where institutional care, with its supervision and management, is possible. It is always a difficult and painstaking procedure to carry out a satisfactory and reliable psychoanalysis, and this is essential before efficient psychotherapeutic measures can be applied. It is always difficult, often impossible, to acquire and maintain satisfactory psychic control of these patients in their home environment or in the environment where the illness has developed. In addition it is frequently much more difficult to regulate the influence of the environment, often exercised with the best intentions and the purest motives, but at the same time the most harmful results, than it is to manage the patients themselves, hence the necessity of absolute isolation to which reference has already been made.

Organotherapy as yet has not produced any results that offer much encouragement along these lines. If it should be finally shown that certain disturbances of the functional interactivity of the internal grandular secretions are more or less responsible for producing the symptom-complex under consideration, and if it should be determined what brings about those disturbances of glandular activity, it may be possible that a therapy along these lines will be developed, but as yet very little is offered. True, in thyroid gland conditions we find some evidence of this possibility, but at best it must be admitted that this phase of it is as yet in its infancy.

In conclusion, something should be said concerning prophylaxis. In children manifesting neurotic tendencies it is a mistake to remind them constantly of their inherent tendencies, either by direct assertion or by discussion of their condition with others in their presence. In such individuals there should be inculcated regularity in habits, deliberation and regulation in all of their physical activities, and the exercise of control over their emotional life. As

stated when discussing the etiological factors instrumental in bringing about the neurasthenic state, the foundation is often laid by injurious tendencies and habits inculcated by improper and unwise education and training, and such individuals should not be called upon to meet conditions suitable only for the normal child, and applicable only to such. More careful consideration must be given children so endowed in preparing for them special methods of training and education.

HUME-MANSUR BUILDING.

THE CANCER ENIGMA.

BY ROBERT BELL, M.D., F.R.S.P.S.,

LONDON, ENGLAND.

PHYSICIAN IN CHARGE OF CANCER RESEARCH, BATTERSEA HOSPITAL, LONDON.

THE medical fraternity would seem, from lack of proper guidance, to have lost its way in a maze formed by a network of theories and conjecture bearing upon the natural history of cancer, these having been arrived at and resulted in such a variety of so-called conclusions that bewilderment and perplexity militate against our obtaining a sane view of the situation.

The unfortunate circumstances are that the majority of these theories rest upon the assumption that they are worthy of being accepted and adopted as "working theories," whereas they would appear to be more comparable to blossoms of the imagination rather than to the fruits of careful research.

To name a few of the theories above referred to and which, so far, have failed to be productive of an atom of evidence to suggest even that they have in any way advanced our knowledge of the subject at issue, I may be permitted to mention the assertion which has been made by not a few writers that the disease is due to a germ of one kind or another, or to a parasite, and this, notwithstanding the fact that neither of these entities has so far been recognized by the most ardent of microscopists. Yet many aver that this negative result is of no consequence, and that there can be no doubt but that a microbe of one form or other is the factor at work; moreover, that this being the case—where there is no case—accounts for cancer being of an infectious and contagious nature—which is also a fallacy. Among other theories advanced may be mentioned eating salt bacon, and the employment of salt, as a condiment, acting as predisposing causes of the disease; another that the presence of lime in the blood is a predisposing cause, notwithstanding the fact that the bones of the body are composed, for the most part, of phosphate of lime. Again, exposure to the rays of the sun—one of God's greatest gifts—have, by at least two writers, been stated to be factors in the production of cancer. Tomatoes and other wholesome edibles also have been charged as responsible for the prevalence of this, so far, intractable disease, to which may be added many other equally innocuous substances, without evidence to support such conditions being forthcoming; though these have been adjudged as guilty in promoting the incidence of the malady, while the more palpable causes have received little or no attention. Therefore, the scourge, though avoidable, is allowed to continue its ravages unchecked.

Now all these, from my point of view, untenable theories have been advanced and circulated since that pioneer of the science of pathology and master of his subject, Sir James Paget, stated, "The condition of the blood is the predisposing cause of cancer," and I have no hesitation in affirming that his opinion still is accepted as final by all who have given prolonged study to the subject. The question therefore arises: What is the *fons et origo* of this pernicious condition of the blood stream which converts it into a predisposing cause of cancer?

"The blood is the life" is a trite saying, and with that statement the matter, with some people, would appear to end. It, however, must be admitted, even by the most casual, that healthy life is compatible only with an uncontaminated blood current. And it is obvious that if the blood can be maintained in a pure conditions the cellular tissues would, in consequence of their component cells being supplied with the most invigorating form of nourishment, be enabled to carry on their functional activity in the most perfect manner, and therefore be capable of resisting the invasion of disease no matter what form it might assume. In short, belief in the existence of a morbid condition in an individual in such happy circumstances would be an insult to one's intelligence.

It is impossible, with our present information, to be oblivious to the fact that the healthy vital condition of the blood, and therefore one's freedom from disease, is dependent upon the more or less functional activity of the endocrinic (internal secretion) glands, to each of which is allotted the presiding influence over certain dominant factors concerned in maintaining, by their harmonious efforts, a united front against the access of disease in its multitudinous forms. And in this connection I may be permitted to emphasize the supreme importance of taking advantage of the means within our reach to give every possible impetus to these important organs by, in the first place, attending with the greatest solicitude to the expectant mother's health, and also to the child's diet and hygienic welfare, so as to give it a good start in life, and exert a more powerful influence in promoting and establishing a healthy and vigorous maturity than can ever be obtained by the fussy and futile efforts at present so much in vogue, most of which are the outcome of immature knowledge of the subject so many would-be reformers have taken in hand.

It goes without saying that these endocrinic glands are entirely dependent upon a pure blood supply to enable them to extract from it the elements necessary to produce their special secretions, which are intended to fortify the identical fluid from which these elements were obtained. Now, if the blood stream, which is circulating in these glands, contains toxic material, this having been conveyed to it either by the mouth, from the air, by water, or by absorption from the colon, it stands to reason that the secreting power of these glands must be handicapped *pro rata*, and the general health will suffer accordingly. And it is not difficult to comprehend that if this toxic condition of the blood is permitted to continue for a prolonged period, not only will the secretions of these glands be decreased in quantity, but also suffer in quality,

and the enfeeblement, which might have been recovered from, had measures been adopted to restore the quality of the blood to its healthy condition, will, otherwise, tend to develop into disease.

It is in such circumstances that the question of diet, also the sanitary condition of the colon, fresh air, and a clean skin, come into such prominence; and in this connection I venture to call especial attention to the skin as an organ of excretion, being quite equal, I may add, to that if the kidneys in many essential points. Take, for example, the part it plays in the endeavor to get quit of the poisonous material circulating in the blood during an attack of any of the eruptive fevers, and in acute rheumatism. Moreover, we often have experience of the disastrous effect its activity produces upon its own cuticle, due to the effect of the irritant in process of being eliminated; in scarletina, for example, and other of these fevers. Moreover, its power of elimination is easily recognized by the odor of the perspiration in rheumatic fever. Again, we can never overestimate the value of the skin as the means of regulating the heat of the body, when it is exposed to high temperature, by evaporation from its surface. Therefore, I submit that a clean skin is one of the essentials to perfect health.

The defensive power of the cells of the body against disease is entirely dependent for its potency being maintained upon strict observance of the above conditions. This can easily be effected by employing a little common sense, and by a successful attempt to obey nature's (which are God's) laws; these laws can never be *broken*, although they may be ignored at times with seeming impunity. On the other hand, if broken, they will, as sure as fate, *break* the transgressors, and this result is apparent on every hand, as exemplified by the terrible prevalence of disease from cancer downwards, and by the evidences of senility in place of a green old age; all of which demonstrate the fact that he who attempts to break nature's laws will most assuredly be the victim of his own temerity.

Materia medica is the oldest example of the "wait and see" policy, and it only requires a little wholesome self-restraint, and as I have already mentioned, the exercise of common sense to convert it gradually into an antique.

Man, as is the case with other members of the animal kingdom, is entitled to a longevity equal to eight times the length of time occupied in attaining his maturity, which may be taken as twenty years. Therefore, I believe it is within the province of reason that if he strictly adheres to the observance of nature's laws he should enjoy good health until he celebrates his 160th birthday.

I may be permitted to state that the above observations are the outcome of twenty-five years' close study of several hundreds of cancer patients that have come under my care, with the result that I have no alternative but to pronounce it as being a self-inflicted disease. Many writers on the subject have referred to it as a disease of civilization; and this is, unfortunately, too true. But does this not imply that it is our conventional mode of living that is at fault? For my part I feel it is to a very considerable extent—if not altogether—the most potent factor or rather combination of factors responsible for the terrible prevalence of this scourge. It is no use mincing matters, so we must stare glaring facts in the face, and make up our minds to mend our ways if we mean to exterminate—which is quite within our power—this terrible penalty inflicted upon disobedience to those physiological laws upon which the healthy functional activity of our various organs depends. And we know, to our cost, by the numerous ills that attack our flesh, how exacting these laws are, and permit me to add in passing that it is a grave mistake to accept the dogma that flesh is *heir* to any such ills, which is so plausibly and extensively quoted. I repeat, those who attempt to break nature's laws shall assuredly only succeed in being broken by them.

If we look around we shall find that man is the only member of the animal kingdom who destroys his food value by cooking. He ignores the fact that the calls of his body, like those of every living creature, are only able to retain a healthy functional activity if they are provided with pabulum from which the living principle has not been destroyed by heat. Moreover, the natural organic salts must also be left intact, these also being essential to healthy cell metabolism. In short, a considerable amount of our food should be consumed in its natural condition, which is already sufficiently cooked for us by the sun. In fact, our cells, if they are to be continued in healthy vital activity, must be provided with *live*, not dead, material. The importance of this I shall endeavor to prove later on. It is quite a mistake to imagine that ripe fruit and vegetables are more difficult to digest in their natural condition than when cooked. The very opposite is the case. (Just try this form of diet on a chronic dyspeptic and you will not regret it.) Of course, it goes without saying that complete mastication must be employed. Even unfired bread is preferable to baked, but in any case whole wheat meal, and that stone ground, only should be allowed. As for peas, I very much prefer to eat them fresh out of the shells. Some people may view this as a Spartan diet, but this conclusion has been arrived at before giving it a trial. I don't wish, however, to burden my readers with a lecture upon dietetics, but I can assure them a diet based upon the above principles will go a long way towards eradicating cancer, not to mention other maladies due to indulging the palate more than the stomach, the normal capabilities of which are limited.

During the period dating from 1894 a very considerable number of cases of cancer in its various forms and positions have come under my observation, many of which had been turned out of hospitals as being inoperable. And I am convinced that a judicious dietary has exercised a more potent influence in arresting the disease and in effecting a cure than the supplementary measures simultaneously employed. And I may safely affirm that, had the conventional diet been permitted to be indulged in, not one of my cases would have recovered. Indeed I am daily becoming more and more convinced that a reformed diet has a greater therapeutic effect than the combined accessory measures employed in the treatment of not only cancer but many other diseases as well. And it will be admitted that this view is not unreasonable when we consider so many diseases take origin from loading and, frequently, overloading the stomach with material

which it is impossible for it to utilize in a satisfactory manner.

I remember the case of a patient suffering from carcinoma of the rectum, being carried into a nursing home in the country, to which I was called in consultation. It was the first time I had seen the patient. There could be no possible doubt of the diagnosis. She was in such a state of emaciation and so weak that she was unable to sit up even in bed. Such being the state of affairs, it will be admitted that the case seemed hopeless. She, however, was a most determined person, and would not consent to undergo any treatment except by diet. She was, therefore, put upon a diet restricted to fruit and vegetable juices with fresh milk superadded. Fortunately it was summer time and there was an abundance of fruit and vegetables at hand. The result of this was that she speedily began to put on flesh, the disease was arrested, and complete convalescence was attained in five months from the date of her admission to the home, and she was able to run a distance of 300 yards round the grounds attached to the home.

The unfortunate circumstance is that ignorance of food values is so prevalent, and that flesh meat is considered to be more nutritious and sustaining than vegetable material, and this notwithstanding the fact that it is the product of the lower grades of vegetable matter.

Of course one employs therapeutic aids towards fortifying the blood, but these are only of second rate importance to diet. Yet they have their value. These, in my opinion, should consist mainly of organic salts, together with a preparation of the expressed juice obtained from vegetables, and occasionally from seaweed, in its most concentrated form, so that it is reduced to a powdered condition, and then preserved in gelatine capsules in palatinoid form, each capsule containing the equivalent of half an ounce of the *cold* drawn expressed juice of various plants and algæ. (The latter I have found useful in the treatment of goiter.) These are administered with, or after, meals. Another valuable source of this preparation is yeast, reduced to a powder by evaporation without the aid of heat, this also being administered in palatinoids. Two or three of these may be swallowed after meals. It is, as a rule, in cancer subjects that hypothyroidism exists, when the addition of half to one grain of thyroid extract is advisable. Indeed, I have had every reason to attach great importance to thyroid medication in this malady; so much so, that it has proved in my experience to be in many instances almost a specific when combined with a regulated diet. At all events, it has been the means of accelerating recovery.

One illustration will be sufficient to demonstrate its value. This was the case of a poor woman, who, after having undergone a laparotomy, but without anything more having been accomplished except that a correct diagnosis of carcinoma involving the wall of the stomach, with extension to certain glands, was obtained. This diagnosis the registrar of the hospital kindly sent to me. On being discharged from the hospital she was told that her case was hopeless and that she would probably not live more than two months. She was brought under my care immediately upon leaving the hospital, being then in a most attenuated condition, having lost thirty-two pounds in weight, and being unable to retain any ordinary food. She was put upon fruit and vegetable juices, and egg flip composed of the white of an egg beaten up in a teacupful of fresh milk. Of these articles very small quantities at a time were taken, alternately, every two hours. Therapeutically, a teaspoonful of elixir of thyroid (gr. v. to the teaspoonful) was administered three time daily. Within a month gradual improvement began to take place, which, fortunately, was maintained, until at the end of seven months the patient had regained her former weight, and was able to retain and digest a normal quantity of food in sufficient quantity at meal times without intermediate feeding.

While the above constitutes what might be designated my routine treatment, there are instances where I have obtained evidence that recovery might be hastened by employing, in conjunction with the foregoing, one or other of the following measures: For example, in breast cases, considerable benefit has been afforded locally by exposing the tumor daily, if possible, to a strong current of air heated up to 170 deg. or 180 deg. Fah., great care being taken not to scorch the skin. This is quite possible if the hot aid douche is not allowed to play too long on one portion of the tumor at a time. It is also essential that the hot air be driven under some pressure, otherwise the heat will not penetrate the skin. I have also found this of considerable service in epithelioma. In addition to the above, gratifying results have been consequent upon the subcutaneous injection of 2 c.c. of magnesium colloid. This should be boiled for a few minutes to render it sterile. The injection gives little or no pain, and may be repeated two or three times a week. I have also obtained very satisfactory results, especially in sarcoma, from the injection deeply into the gluteals of 1 c.c. of atoxyl in iodolysin. If the latter is not available distilled water might, with little disadvantage, be substituted.

15 Half Moon Street.

BLOOD COUNTS IN DIAGNOSIS AND TREATMENT.

By HORACE GREELEY, M.D.,

BROOKLYN, NEW YORK.

While all admit that blood counts are indispensable in the primary blood diseases, the fact that they are made in such a small proportion of other conditions in which they supply information of great value testifies that the practice of regarding such work as a superfluous refinement is common.

Attending physicians, nowadays, may rarely base a diagnosis of anemia upon an inspection of the lips and conjunctiva, but there are certainly many cases treated for blood impoverishment with iron and other therapeutic agents without a single examination of the blood having been made. In such cases not only is the diagnosis in doubt, but also the degree of improvement, if any, effected by the medication.

In a case with nothing more definite in the symptoms than a recent advent of poor health one might, by neglect to make a blood count, easily miss an

incipient case of one of the primary blood diseases —pernicious anemia or leukemia.

Then there is the host of infectious diseases and localized inflammatory conditions in which marked and sometimes distinctive changes in the leucocytes occur, a knowledge of which is often of great assistance in the diagnosis; and, in the second class of conditions, particularly, in the prognosis, and as an index of the need for surgical intervention. Finally, there are many obscure cases of illness upon which light may be shed by a blood count—in any event such a procedure always excludes some conditions which could cause the symptomatology.

With the idea, therefore, of calling more attention to changes in the blood in various common conditions, and the advantages of blood counts in connection therewith, the present article has been written.

Blood Counts in Health.—As a preliminary to a discussion of the significance of changes in the blood count, a table is given in which the origin and usual numbers of the cellular elements of the blood and concentration of hemoglobin is listed.

THE BLOOD IN HEALTH.

Element.	Origin.	Quantity in Health		
		Children (Under 12).	Women.	Men.
Erythrocytes	Bone marrow	3,500,000-4,500,000	4,500,000-5,500,000	4,500,000-6,000,000
Hemoglobin	Erythrocytes	11.5 grams in 100 c.c. of blood	13.5 grams	14.5 grams
Placques	Bone marrow (megacaryocytes)	150,000 in 1 c.mm.	150,000	150,000
Leucocytes		8,000	8,000	8,000
		Per cent.	Per cent.	Per cent.
Polymorphonuclear neutrophiles	Bone marrow (granular myelocytes)	48.0	60.0	60.0
P. basophiles*	Bone marrow (granular myelocytes)	0.3	0.3	0.3
P. eosinophiles	Bone marrow (granular myelocytes)	3.7	3.7	3.7
Small lymphocytes	Lymphatic glands	30.0	25.0	25.0
Large lymphocytes (younger lymphocytes)	Lymphatic glands	10.0	3.0	3.0
Large mononuclears and "transitionals"	Endothelium of lymph spaces, particularly of spleen. So called "transitionals" are most probably young large mononuclears showing indented nuclei.	8.0	8.0	8.0

*Number found depends much upon technique of staining.

The "color index" in a given blood examination, being the quotient of the hemoglobin percentage of the normal divided by the red cell percentage of the normal, is supposed to serve a useful purpose in showing the relative values of red cell numbers and their hemoglobin contents. Since necessity is said to be the mother of invention, this term is to be blamed entirely upon a father, as so practical a mother could never be credited with such a useless and misleading creation. Thus while we find that the color index of normal blood is around—

$$\left(\frac{100,\ \text{erythrocyte per cent.}}{100,\ \text{hemoglobin per cent.}}\ \text{equals}\ 1\right)—$$

we also find that the "color index" of the disease most markedly affecting red cells and hemoglobin, pernicious anemia, approximates the same, since the erythrocytes and hemoglobin decrease together, and so long as the percentages of these elements are about equal we will have a normal "color index," a result which well illustrates the worthlessness of the figure. One well understands the meaning of a red cell count of 2,500,000 (50 per cent. normal), and the relation thereto of a hemoglobin percentage of 50, or whatever it may be, is seen at a glance, since there is no difficulty in recollecting the average normal number of erythrocytes, and the arithmetic necessary in order to figure that 2,500,000 is 50 per cent. of 5,000,000 is easily carried on the fingers of one hand. While the proportion $\frac{50}{50}$ if given in a report, might save this mental calculation, the quotient 1, the "color index," fails to convey any idea of the condition of the blood examined. For these reasons no further mention will be made of this term.

Nonpathologic Variations in the Blood Count.—Repeated counts (for the erythrocytes counting the contents of 200 small squares and for the leucocytes of 100 large squares of the apparatus) of either the red or white blood cells of the same person, made at the same time, vary within 2 per cent., owing to mathematical considerations.

In cold weather, and after either hot or cold applications or vigorous rubbing, a greater concentration of cells in the vessels of the part affected develops so that variations in the count, even as great as ten per cent., may be so explained. Blood drawn from dependent parts, such as the foot, or from congested (actively or passively) areas shows a like increase of cells.

The above considerations apply to both red and white cells.

The slight increase in the leucocytes of the blood during active gastrointestinal digestion, which may reasonably be ascribed to the mobilization of those elements for their function in destroying noxious elements absorbed with protein food, is within a similarly small percentage.

The average number of red cells is greater in inhabitants of high altitudes (5,000 feet) than in those living near sea level, by often as much as one-third. Infants, during the first few days of life, frequently give counts of erythrocytes as great as 6 to 8 million per cubic millimeter. They also usually show a slight neutrophile leucocytosis.

Women are usually stated to give counts showing the red cells to be on the average 10 per cent. less than in the case of men, but there are many exceptions to this supposed rule, and as 10 per cent. is within a normal physiological variation which covers the periodical blood loss due to menstruation, no allowance should be made on account of sex.

Old age in itself probably has no direct influence upon the blood elements. However, since chronic disease becomes common as persons advance in life so do blood changes, such as secondary anemia, directly due to these ailments.

The blood placques, so far as is known, show no physiological variation in their number (estimated to be normally from 100 to 300 thousand in a cubic millimeter), except in women after the menstrual period and after parturition, when they are usually considerably increased.

THE BLOOD IN DISEASE.

Element.	Normal Adult Blood.	Infection Leucocytosis.	Secondary Anemia, Including Hodgkin's Disease.	Chlorosis.	Pernicious Anemia.	Leucocythemia.
Erythrocytes	5,000,000 per c.mm	No change.	Moderate decrease; changes in character of cells variable.	Moderate decrease.	Great decrease (as much as 80 per cent.) Cells irregular in shape, and staining; nucleated cells present.	Considerable decrease. Cells vary in character as in pernicious anemia. Nucleated cells constant.
Hemoglobin	14 grams in 100 c.c.	No change.	Moderate decrease.	Marked decrease.	Decreases with cells.	Decreases with cells.
Leucocytes	6,000–10,000	Increased, rarely to over 50,000.	Depends upon associated conditions.	No change.	Decreased.	Marked increase (to 100,000 or 300,000).
Polymorphonuclear neutrophiles	60.0 per cent	Increased.	.....	.....	Decreased.	Decreased, their bone marrow precursors (neutrophile myelocytes) usually make the bulk of the increase in myeloid variety.
Eosinophiles	0.7 per cent.	Decreased.	.....	.....	Decreased.	Increased in myeloid variety.
Basophiles	0.3 per cent.	Decreased.	.....	.....	Decreased.	Increased in myeloid variety.
Lymphocytes	31.0 per cent.	Decreased. (Increased when glands are involved.)	.....	.....	Increased.	Greatly increased in lymphatic variety.
Large mononuclears (including "transitionals")	8.0 per cent.'	Decreased. (Increased early in typhoid, and in malaria.)	Increased in Hodgkin's disease.	.....	No change.	Decreased.
Placques	200,000	Variable.	Variable (increased in Hodgkin's disease).	Variable.	Decreased.	Increased.

NOTE.—Terms "increased" and "decreased," as applied to varieties of leucocytes in this table, relate to percentages.

Pathological Variations in the Blood Count.—Erythrocytes.—After extensive hemorrhages there is, of course, a temporary diminution of the red cells in proportion to the blood lost. In good health this is rapidly made up, and during the most active part of the process a blood examination may disclose, besides the reduced number of red cells, some that have entered the blood stream prematurely in the nucleated form, from the bone marrow.

The poisons of chronic disease, such as lead poisoning, malignant growths, leukemia, etc., vitiate the plasma so that the usual supply of normal erythrocytes is interfered with and a slight to moderate anemia results. The changes in the character of the red cells in such conditions are usually slight, variable, and not pathognomonic.

In that clinical condition of uncertain etiology known as chlorosis a similar diminution in the number of the red cells is observed, but the chief change is in their quality, since a marked reduction in the content of hemoglobin is constant.

It is in pernicious anemia that the red cells are most markedly affected by disease. As the cause of this malady is unknown, be it toxin with special affinity for the erythrocytes or microbic infection of the bone marrow, and the commonly sudden onset and rapid progress suggests an infectious origin, one cannot certainly diagnose the condition until it is well along and, perhaps, as great diminution of the red cells as 50 per cent. has occurred. Of course, besides the reduction in number, these cells show the effect of disease by irregularity in size, shape, and even in staining, and some of their progenitors of the marrow, nucleated red cells, are found in the blood stream. The effect of the malady upon the bone marrow is such that, in well developed cases, all the other blood cells (granular leucocytes and placques) that originate therein are also considerably reduced in number.

Leucocytes.—A total leucocyte count of over 7,000 per cubic millimeter may be regarded as a pathological leucocytosis if there be a simultaneous disturbance in the ratio of the five varieties of these cells; otherwise 10,000 or even 12,000 may not be said to indicate disease.

Infections quite generally produce leucocytoses which vary, frequently, according to the nature of the infectious agent, according to its location, according to the extent and acuteness of the process, according to the stage of the disease, and according to the activity of the patient's leucocytic resistance. The extent of a leucocytosis is usually to not more than 30,000 leucocytes per cubic millimeter of blood.

Typhoid fever, typhus, tuberculosis (without secondary infection), malaria, measles, the tropical diseases, kala-azar and dengue, are commonly said to show a diminution in the leucocyte count. However, the facts seem to be as follows: In typhoid, at the onset and for a few days thereafter, there is usually a slight increase of from 2,000 to 3,000 in the leucocytes. This increase is due entirely to increased production of cells by the lymphatic glands (including Peyer's patches) caused by the stimulus from the irritation of the typhoid bacilli present therein. Frequently there is a coincident increase of the large mononuclear, including "transitional," leucocytes, the cause of which is evidently the early effect of the infection upon the spleen, the supposed place of origin of these cells. There is a simultaneous reduction in the polynuclear neutrophile variety of leucocyte, probably due to the greater effect of the typhoid poison upon these cells and their parent cells in the bone marrow. A typical count during the first few days of an attack of typhoid is as follows:

Mrs. E. (patient of Dr. B. Vogt, Woodhaven, N. Y.), sick seven days, Widal positive, 1-40, in 20 minutes. Total leucocytes, 9,725; polymorphonuclear neutrophiles, 47 per cent.; eosinophiles, 1 per cent.; basophiles, 0; large lymphocytes, 17 per cent.; small lymphocytes, 33 per cent.; large mononuclears, 2 per cent.

Later in the course of the disease, as prostra-

tion of the patient and destruction of the lymphatic and bone-marrow cells progresses, a subnormal number of leucocytes is found. After convalescence begins, all the leucocytes that have fallen in number during the course of the malady increase, and this reaction always carries the count considerably beyond the normal, producing a distinct leucocytosis.

In typhus fever the leucocyte count is similar to that in typhoid fever, and varies in much the same fashion.

In miliary tuberculosis a great fall in the normal leucocyte count (affecting principally the polynuclear neutrophiles) is met. This is, of course, due to the swamping of leucocyte resistance and production by swarms of tubercle bacilli. That a pure tuberculous process is capable of inciting a leucocytosis is seen in cases of exudative tuberculous meningitis. Glandular tuberculosis causes a distinct increase in the lymphocytes unless extensive destruction of glands has taken place. In cases of tuberculosis, as of the lungs, where secondary invaders (micrococci, etc.) are present, the effect of the disease upon the leucocytes is a resultant of the specific action of all the organisms concerned.

The effect that malaria has upon the leucocyte count seems to be due to the damage done the bone marrow by the infection. However, there is no distinct lowering of the leucocyte count except in severe cases. In malaria and some other protozoal infections there is often a characteristic increase of the large mononuclear leucocytes to 10 per cent. and over.

During the incubation of measles there is a slight polymophonuclear neutrophile leucocytosis, which has disappeared by the time of the onset when a distinct reduction of the count of these cells is usually found.

During the height of the tropical diseases, kala azar and dengue, the leucocyte count often falls below 2500 per cubic millimeter.

Diseases which cause a destruction of the leucocyte-forming organs (bone marrow and lymphatic glands), such as pernicious anemia and general lymphatic-gland carcinoma, naturally cause, when advanced, a distinct reduction in the total number of cells originating in the part affected.

Any infection, which ordinarily causes leucocytosis, if fulminating, may overpower the leucocytic-reaction mechanism and show a reduction instead of an increase in the number of these cells.

Chronic alcoholism, through injury to the leucocyte producing areas, may be the cause of a reduction in the leucocyte count.

Various drugs, such as benzol and large doses of quinine, act to reduce the number of leucocytes. The former, benzol, is so active that after the administration of a few doses, in cases of leukemia in which the blood leucocytes have increased to as much as 200,000 per cubic millimeter, the count of these cells may fall below 5,000 per cubic millimeter.

Except with diseases that tend to attack or irritate specially the lymphatic glands (tuberculosis, typhoid, syphilis, plague, etc.) and thereby directly affect the production of the lymphocytes, all infectious leucocytoses are of the polymorphonuclear-neutrophiles, and, therefore, due to the effect of soluble poisons upon the cells of the bone marrow. Typically illustrative of this is the leucocytosis that promptly begins at the onset of lobar pneumonia, which usually regularly increases up to the crisis of the disease, and then promptly declines. In this and other infections the degree and continuance of the leucocytosis are of prognostic value, since with an apparently mild case a moderate leucocytosis indicates good resistance; with an apparently severe case a marked leucocytosis the same; while serious symptoms with a slight or a diminishing leucocyte count point to a poor or a failing resistance.

One of the most important uses to which the information obtained from a leucocyte count can be put is in the diagnosis and prognosis of infections connected with surgical conditions. In addition, information so obtained is of great value in judging of the need for immediate operative interference, as in acute appendicitis, mastoiditis, etc.

While a marked increase in the total leucocyte count indicates only an active infection and good resistance, variation in the percentage of neutrophiles is a reliable guide to conditions at the focus of inflammation. As a rule, when suppuration or gangrene impends, as of an acutely inflamed appendix, a marked and hourly increasing rise of the neutrophile percentage is to be found. It may be confidently stated that no such development ever threatens unless this percentage is over 80. As the percentage rises above 80, the probability of the presence of a purulent or gangrenous process increases. If the rise in the percentage of neutrophiles is of greater degree than the rise in the total leucocyte count poor resistance is indicated; and, consequently, any neutrophile percentage above 80 with a low total leucocyte count (under 12,000) points more strongly to suppuration or gangrene than a similar neutrophile percentage with a proportionate increase in the total number of leucocytes.

Progressive extension of an inflammatory process, such as local peritonitis or mastoiditis, is indicated by progressive rise, both in the total leucocyte count and in the percentage of neutrophiles.

In inflammatory processes of low grade, such as chronic appendicitis or arrested (not extending) acute inflammations of small extent—mastoiditis, etc., one finds but small increase in either the total leucocyte count or in the neutrophile percentage.

Besides infectious processes, there are certain other causes for neutrophile leucocytosis. Thus any severe hemorrhage is immediately followed (within 24 hours) by an increase in these cells. Such a leucocytosis may reach 20,000 per cubic millimeter, and lasts as long as 24 hours after the bleeding has stopped.

In practice, physicians frequently have to differentiate between intraabdominal hemorrhage, such as may be caused by an extrauterine pregnancy and other conditions. When such a hemorrhage is suspected, a leucocyte count is of the greatest assistance, as a neutrophile leucocytosis without fever, or with a very slight elevation (within one degree F.) of temperature, is strong corroborative evidence.

Ether or chloroform narcosis causes an apparent

slight leucocytosis (due to increased mobilization rather than to increased production) subsiding, however, within a few hours.

Whether we believe that eosinophiles are modifications of the neutrophiles or not, we recognize that certain variations in their numbers are of importance in differential diagnosis.

Increase of these cells to greater than 5 per cent. of the total leucocytes is usually indicative of animal parasite infection (such as trichinosis, tapeworm, hydatid, etc.) unless otherwise explainable. Thus in severe bronchial asthma eosinophiles have been often found to exceed 10 per cent., and they are considerably increased at the height of an attack of scarlatina, or during the course of some skin diseases such as pemphigus. The eosinophiles are said to be more numerous in the blood of children, but this is most probably due to the greater prevalence among them of the conditions known to cause increase of these cells. The increase of eosinophiles in leucocythemia will be mentioned later.

No importance has been attached to variations in the basophile count.

The lymphocytes are specifically increased, as previously explained, in any condition irritating the lymphatic glands or producing hyperplasia thereof, and the number found in the blood is consequently abnormally high in nasopharyngeal inflammations, in many acute intestinal disorders (especially of children), and in whooping-cough where the lymphocytes not uncommonly increase 5 to 10 fold; often also, at the onset of typhoid, and always during convalescence.

During the acute glandular involvement of early syphilis these cells are moderately increased, sometimes doubling in number. In toxic goiter there is a slight increase, as also in beginning cases of Hodgkin's disease. The lymphocytosis of leukemia will be considered later. An abnormally low number of lymphocytes indicates a destructive affection of the lymphatic glands, such as may be caused by extensive tuberculosis.

The large mononuclears (including so-called "transitionals"), as previously mentioned, are often found to be increased in typhoid and malaria and some other tropical protozoal infections.

When we find a marked increase of leucocytes (over 30,000) and a differential count not typical of any known infection, and no symptoms of such a process, we are justified in suspecting beginning leucocythemia (leukemia), *provided* the differential count shows the presence of unusual numbers of lymphocytes or of bone-marrow cells in considerable numbers. Since both varieties of leucocythemia tend to be progressive, confirmation or refutation of the diagnosis is always to be obtained through a later blood count, which, in the case of leucocythemia, would show a still greater increase in numbers of the cells concerned. However, cases of leucocythemia are usually not recognized until the leucocyte count is over 100,000 per cubic millimeter.

In the variety of leucocythemia (lymphatic) in which the overproduction of leucocytes arises from the lymphatic glands and other lymphatic tissue, we find a great increase of the lymphocytes (either small, large, or both). This increase has to be distinguished from the temporary and moderate increase of the lymphocytes due to known irritants, such as an infection of a chain of glands, hyperplasia of such glands from any cause, etc., previously mentioned. In either acute or chronic lymphatic leucocythemia, the lymphocyte increase is progressive until the numbers of these cells in the blood reach several hundred thousand per cubic millimeter, and this fact is sufficient to prevent mistakes in diagnosis. The rare condition denominated malignant lymphoma is probably but an atypical early-stage lymphatic leucocythemia.

Diagnosis of leucocythemia due to affection of the bone marrow depends upon finding the white-cell increase to be due to increased numbers of those leucocytes which originate in the bone marrow, and especially the presence of the parent form of these cells, myelocytes (mononuclear granular cells) which usually appear preponderatingly neutrophile, but which may be principally eosinophile or even basophile, and varying numbers of nucleated red blood cells. In acute and late stage myeloid leucocythemia, nongranular bone-marrow cells (myeloblasts) are also common.

Placques.—As the function of the platelets is to inaugurate the clotting of the blood by their disintegration, we would expect to find them increased, as we do, in all conditions in which hemorrhage has occurred. After such loss of blood as usually accompanies a major operation it is common to find the platelets increased 2 or 3 fold.

From some studies published in 1915 by Duke (*Archives Int. Med.*, Nov., 1915) and in 1916 by Minot and Lee (*Archives Int. Med.*, Oct., 1916), we may conclude that in purpura hæmorrhagica there is an almost complete absence of placques from the blood. It seems that purpura hæmorrhagica may be brought on by bacterial infection, such as Vincent's angina, illustrated in the case of a physician reported by me (*Am. Journal Med. Sc.*, May, 1919) who died from a chronic infection with the spirilla-bacillus of Vincent, and the well-known fact that the blood extravasations (of purpura hæmorrhagica) are commonly preceded by an attack of sore throat.

This is in agreement with Duke's experimental demonstration that various bacterial poisons injected into animals reduced the number of placques.

The toxins of bacterial infections generally act to reduce the number of placques during the height of such diseases. For instance, in diphtheria the number of placques is reduced as much as one-half, as a consequence of which convalescence brings an equally great increase, to several times the normal number.

In chronic tuberculosis with hemorrhage (not necessarily external), the placques are much increased.

Blood placques are reduced in number in pernicious enemia and increased in leukemia, greatly so in Hodgkin's disease.

According to Minot and Lee hemophilia is due to an hereditary defect of the placques which, while present in normal numbers, do not disintegrate under hemorrhagic conditions and, consequently, fail to bring about clotting.

140 Clinton Street.

FOCAL INFECTIONS OF THE HEAD AS SOURCES OF SYSTEMIC DISEASES.*

By JAMES JOSEPH KING, A.B., M.D.,
NEW YORK.
ATTENDING LARYNGOLOGIST, HOSPITAL FOR THE RUPTURED AND CRIPPLED; ASSISTING SURGEON, OTOLOGY, NEW YORK EYE AND EAR INFIRMARY; CONSULTANT IN OTOLOGY AND LARYNGOLOGY TO THE FRENCH HOSPITAL.

ASSUMING that the relationship of focal infections to systemic diseases is now an accepted fact, we desire to present in its broader aspects the subject of focal infections of the head as sources of systemic disease and to bring before you several new and important developments.

The subject is not new, for casual observations on this relationship are found in the older literature. In 1789 Eyerlin, of Christiania, in his "Materia Rheumatica ad Tonsillitas," considered the relationship of tonsillitis to rheumatism as clinically evident. In 1818, Benjamin Rush[1] reported a case of rheumatism of the hip accompanied by toothache, which was promptly cured by extraction of the decayed tooth.

For nearly one hundred years after the publication of "Medical Inquiries" by Rush, the literature has little or nothing on the subject. The review of the literature up to 1909 reveals the fact that no scientific proof of the connection between focal infections and systemic diseases had been published. It was clinically evident that certain infectious diseases followed tonsillitis and the same organisms had been found in the tonsils and the secondary lesions. There had been so much clinical evidence up to 1909 suggesting this etiology that scientific proof seemed scarcely necessary.[3]

From 1899 to 1909 over one hundred writers presented clinical evidence linking tonsillar infection to other diseases. In spite of all this clinical evidence, however, the majority of the medical profession remained skeptical up to ten years ago. During the last ten years many scientists, working in different fields, have presented an abundance of evidence to establish the scientific proof. To be more specific, during the past ten years more than fifty authors have contributed data based upon research and clinical work to prove the case from a scientific standpoint.

Under focal infections in the head, we include infections of the tonsils, including all lymphoid tissue in Waldeyer's ring, teeth, gums, nasal accessory sinuses, middle ear, mastoid, and lateral sinuses; in fact, all cavities communicating with the mouth, nose, or nasopharynx are included. Pus enclosed in any of these cavities is, for all clinical purposes, one and the same problem.

Consensus of opinion gives the tonsils first rank in importance as foci of disease; then follow the teeth, with the nasal accessory sinuses and middle ear coming in for third and fourth honors.

The late Dr. N. B. Potter, formerly Professor of Clinical Medicine in Columbia University, said in 1916: "Wherever the infection may be, one or more of the foci of the central cause radiate to a vicious circle of complex pathological conditions and frequently result in life-long invalidism. The list of diseases in which oral sepsis may prove to be of considerable or paramount etiological significance is as follows:[4]

1. Neurasthenia.
2. Neuritis, reflex or remote result.
3. Neuralgia.
4. Myalgia.
5. Myositis.
6. Arthritis, acute, subacute, or chronic.
7. Osteitis.
8. Periostitis.
9. Gout.
10. Basedow's disease.
11. Furunculosis.
12. Sepsis.
13. Endocarditis.
14. Pericarditis.
15. Myocarditis.
16. Chorea.
17. Arteriosclerosis.
18. Meningitis.
19. Pleuritis.
20. Bronchitis.
21. Asthma.
22. Pneumonia.
23. Nephritis.
24. Pyelitis.
25. Cystitis.
26. Gastric neurosis.
27. Peptic ulcer.
28. Appendicitis.
29. Colitis.
30. Cholecysttis.
31. Herpes zoster.

Long as this list may seem, it is not complete—for the writer could add dacryocystitis, conjunctivitis, and urticaria, all of which have been recently cured by removal of infected tonsils. We believe now that practically all diseases are influenced by focal infections.

In a recent contribution, Robert T. Morris, in speaking of gastric ulcer and cancer, urges a search for foci of infections, especially mentioning the teeth.[5]

In an address before the American Medical Association, C. H. Mayo recently said: "Disease, then, is an inflammatory process from infection and the efforts at repair. Infections which produce the greatest number of diseases enter the system by way of the alimentary and respiratory tract. Somewhere in the line, then, of the alimentary and respiratory tracts and in the excretory ducts of the body lie the sources of the entrance of the organisms which terminate life in the majority of instances. In view of what is known concerning infections and their mode of entrance, the infected and diseased mouth and respiratory tract must be looked upon as serious menaces. More general and effective school inspection is recommended as a valuable prophylactic measure. Teeth, adenoids, and tonsils require supervision and correction in the fight against preventable diseases of various kinds. The mouth is the harbor of many varieties of bacteria. The nasal sinuses and chronic mouth and throat infections develop anaphylaxis from the constant poisoning and these results are shown in hay fever, asthma, urticaria, etc. The infected mouth shows a tendency to acid reaction, and this acid change involves an additional danger in cell degeneration of malignant type, from chronic irritation. Bacteria are constantly taken into the stomach in the process of eating."[6]

Rosenow, whose experimental work has done so much to put the relationship of focal infections to systemic diseases upon a scientific basis, has said: "In the light of our present knowledge the argument that infections in the mouth are so common in individuals in apparent health does not minimize their importance. These or other foci are so common in patients suffering rom arthritis, neuritis, appendicitis, ulcer of the stomach, cholecystitis, goiter, etc., and so rare in individuals who have had superb health for years, that their direct etiologic rôle can scarcely be questioned.

*Read before the joint session of the American Academy of Ophthalmology and Otolaryngology at its twenty-fourth annual meeting, Cleveland, Oct. 17, 1919.

"The most common location of the focus or source of infection probably is in the mouth, and the teeth as well as the tonsils must always be carefully examined with this object in mind. However, the question of the focus of infection is a matter not only for the stomatologist or the dentist, but for the general practitioner, the surgeon; every branch of medicine needs to be taken into consideration in order to trace the focus from which the organisms gain entrance to the body. The focus of infection must be regarded not only as the place of entrance of the bacteria but also the place where the organisms acquire the peculiar property necessary to infect."[7]

The results of eradicating foci of infections in the insane by Cotton,[8] is a brilliant chapter in psychiatry. At the New Jersey State Hospital, the average rate of discharge of patients from the Hospital was 42 per cent. That is, for a period of years previous to 1915, forty-two out of every hundred patients admitted were discharged; fifty-eight out of each hundred remained in the hospital for a period of years and died there. Since 1915, Cotton has searched for foci of infections in these insane patients and eradicated them. Since this practice was inaugurated, he has discharged 87 per cent. of the patients admitted to the Insane Hospital cured, or so improved that residence in a madhouse was no longer necessary.

In a notable paper,[9] "Relation of Teeth, Tonsils, and Intestinal Toxemias to Diseases of the Eye," Bell of New York reports a number of eye diseases cured by the eradication of foci of infection.

Reyfuss[11] has proven scientifically what we suspected five years ago.[12] We made the observation in 1914 that patients with stomach complaints—such as dyspepsia or indigestion—with foci of infections in tonsils, sinuses, or teeth, reported almost unanimously that the stomach condition had improved or disappeared after the foci of infection in the head had been eradicated. By his fractional examination of the stomach contents, Reyfuss has found the same infections present in the stomach as were found in the head. He has had remarkable success in the treatment of these stomach and intestinal disorders by having the primary foci in the tonsils, teeth, and sinuses eradicated. In this study, Reyfuss says that the stomach is protected from ordinary infection by the following barriers: (1) Acid secretion, (2) abundant blood supply, (3) more or less constant peristaltic motion, (4) thin coat of mucus lining the stomach wall. The constant swallowing of infected secretions of the mouth, tonsils, and sinuses is, however, sufficient to overcome the natural barriers.

His work confirms that of Smithies, who is quoted in Mayo's article.[6] Smithies, in an examination of the extracts of 2,406 different individuals with stomach complaints (dyspepsia, indigestion, etc.) showed that irrespective of the degree of acidity of such gastric extracts, bacteria were present in 87 per cent.; cocci and diplococci in 83 per cent.; short and long rods, often of the colon group, in 58 per cent.; typical streptococci and staphylococci in 17 per cent.; and *Leptothrix buccalis* in 24 per cent. In fifty-four cultural studies of saliva from dyspeptic patients, streptococci and staphylococci were demonstrated in over 80 per cent.

Carriers of Infection.—The mobilization of our great army and the requirements made upon our medical men to keep the millions of men efficient and in good health have demonstrated the menace of carriers of infection. By cultures made from the throat and nasopharynx of men in the military camps last winter, diphtheria, and meningitis carriers were discovered and isolated. Epidemics of diphtheria and meningitis were thus prevented. Men who developed tonsillitis probably were infected by hemolytic streptococci. In many cases the infection remained in the tonsils, reinfecting the patient as well as others. The writer saw many such cases in Camp McClellan among the 30,000 soldiers there and its real danger was brought home to us during the epidemics of influenza, pneumonia, empyema, measles, and scarlet fever. Death following a variety of acute infections, like measles or scarlet fever, is at present believed to be due to a secondary invader, usually in the guise of a streptococcus, rather than to the primary etiological agent.

The investigations of Pilot and Davis[14] and of Nichols and Bryan[15] point to the tonsils as the principal foci of these hemolytic organisms which are so frequently found in cultures taken from the different parts of the mouth and throat. The evidence is in accord as to the predominance of the streptococci in the crypts of the tonsils, and it appears that the frequency of these bacteria is decidedly less in the throats of persons whose tonsils have been extirpated than in the throats of persons having normal tonsils. Outbreaks of disease due to the entrance of foreign virulent streptococci unquestionably do occur at times, as the epidemics of septic sore throat testify, but in general the streptococcal infections are presumably associated with preexistent foci, like the tonsils, which harbor the bacteria in the body.

Identical strains of *Streptococcus hemolyticus* were found in the crypts of tonsils and in pus from empyema, and in fatal cases of bronchopneumonia, as a complication of measles.

Pilot and Davis[14] thus summarize the possible factors responsible for the secondary streptococci infections: "The existent dormant organisms in the tonsils may become enhanced in their virulence through symbiosis or in some unknown manner by the primary virus (measles, scarlet fever, smallpox) or by the bacteria, such as the *Bacillus diphtheriæ*, the pneumococcus, or the *Bacillus influenzæ*. They may become active through the lowered resistance of the local tissues of the respiratory passages; they may attain increased invasive powers through the lowering of the general resistance of the host overwhelmed by the acute or chronic toxemia. Probably all three factors are combined in certain cases, although one factor often appears to be more important than the others. Thus, in acute respiratory and throat infections, streptococci seem to spread from the tonsillar crypts to the adjacent mucous surfaces, descend into the bronchi and lungs, and enter the blood stream from these tissues. In chronic diseases, on the other hand, the diminution of the resisting power of the blood may admit the streptococci directly into the circulating blood stream without any marked local change in the throat.

Methods of Examination.—The examination of

the tonsil consists of inspection, pressure for pus within the crypts, and plate culture from the crypts.[12]

The examination of the teeth consists of an inspection of the mouth clinically by both physician and dentist, and by a radiograph of all the teeth. Experience has taught us that suspicious areas around the roots of teeth, as revealed by the *x*-ray, are generally worse than the films indicate. The nasal accessory sinuses are investigated by inspection of the interior of the nose, by transsillumination, and by radiographs. The nasal accessory sinuses, with the exception of the ethmoid, may also be studied by irrigating them in the usual way.

Treatment.—The treatment consists in eradicating the focus or foci of infection, practically ignoring which one is the instigator. In the case of tonsils where the crypts are infected with *Streptococcus hemolyticus*, or as in diphtheria carriers, the only effective means of curing them is their complete enucleation. In meningitis carriers, in whom the meningococcus was found in the nasopharynx, the method practised in the army camps consisted in isolation and treatment with such antiseptics as dichloramine-T, 2 per cent., in chlorazone as a spray. At the Rockefeller Institute, the carriers are placed in a humidor whose air is saturated with a 1 per cent. watery solution of chloromine-T. They are kept there for about twenty minutes once or twice daily. A few days of such treatment is unusually effective, as shown by several successive negative cultures. In others more obstinate, or for whom this treatment is too irritant, local applications of such preparations as argyrol and peroxide are used.

In tonsillar infections of the cocci group (streptococcus, staphylococcus, diplococcus), we have found autogenous vaccines of distinct value in raising the patient's resistance. As our experience has increased, we are convinced that many sinus infections are secondary to primary foci in the tonsils or teeth. In such cases the sinus is curable by removing the primary focus, combined with appropriate local treatment.

Conclusions.—1. During the last ten years over fifty writers have presented scientific proof of the relationship of focal infections to systemic disease. This, in addition to the voluminous clinical evidence, has established beyond a reasonable doubt the etiological relation of primary foci of infection to systemic disease.

2. In order to cure patients, the primary focus or foci must be found and eradicated, practically ignoring which one is the instigator. With our broader conception, we endeavor to look over the whole body and correct what is obviously pathological. A certain amount of enthusiasm and generalship in the cooperation of different specialists is eessential. The focus is dealt with according to its location, by methods well known to all of us.

3. The new developments in this field are: (*a*) The broad application of this principle, now accepted by all progressive medical men. (*b*) The proof of stomach and intestines becoming infected by deglutitions of infected secretions from tonsils, sinuses, and teeth. (*c*) The relation of primary foci in the tonsils to the mortality rate in such acute infections as measles, scarlet fever, pneumonia, and influenza. (*d*) Its field of application is unlimited. We are just beginning now to appreciate its value.

ANESTHETICS IN OBSTETRICS WITH SPECIAL REFERENCE TO NIROUS OXIDE.

By RAYMOND C. COBURN, M.A., M.D.,

NEW YORK.

WHETHER the suffering of the parturient woman is a curse of God, or a penalty of civilization, does not concern the physician of to-day in his rôle as such. One of the great aims of the profession is the relief of pain, and while the obstetrical patient has not received her proportionate consideration heretofore, the time has now come that she may, and should, be placed upon the same plane in this respect as her more fortunate surgical sister.

The fundamental requirements for anesthetics in obstetrical practice are widely different from those in general surgery, hence the anesthetics and methods of administration must likewise be varied to fulfill properly the special requirements in this particular field. Failure to differentiate between the proper adaptations for the surgical patient and for the obstetrical patient has been the cause of much of the complacency with which the travail of the parturient woman has been viewed. The average obstetrical patient to-day is permitted to suffer far more pain than her primitive sister and progenitor endured, while her surgical sister, not because she is more deserving, is afforded complete relief. The profession ought to consider it a special duty to extend to mothers the same service in this respect it extends to surgical patients. Not to attempt to do this when it is possible shows lack of the higher appreciation of motherhood.

The pain of the parturient patient, for the most part, is intermittent in character, and extends over some hours, with considerable longer intervals without pain than with it. Even if her physiology, especially that concerned in elimination, is normal, it is close to pathological, on account of the ever-increasing burden that has been thrown upon it for months. In addition, there is the baby and its welfare. These are all very important matters to consider in connection with anesthetics.

Chloroform formerly held the same relative position in obstetrical practice that ether held in general surgery. Latterly, ether has been recommended in obstetrical work in preference to chloroform. But neither of these anesthetics fulfills the special requirements of parturition except for a brief time at the end of the second stage of labor, that is, while the head is passing over the perineum, and for the repair of the lacerations, if any occur. If ether or chloroform is given in the earlier stages, the force and frequency of the contractions of the uterus are decreased, greatly decreased, if either anesthetic is given to the extent of relief of the patient of any consequence. Besides, the period for which relief is needed extends over considerable time, especially in the primipara. Ether and chloroform, when given over a considerable period, further impair and irritate the organs of elimination, being in themselves very toxic; and, given at a time when the eliminating organs have been overtaxed for months, their administration over a considerable period to the obstetrical patient is more questionable than their administration to the average surgical patient. Ether and chloroform, inhaled for a length of time, lower the patient's vitality. This is clearly established scientifically by the lowered blood pressure that follows their administration by the usual methods. This lowering of the blood pressure, or translating it into its real meaning, this lowering of the patient's vitality, does not cease with the withdrawal of the anesthetic, even with ether, but the blood pressure continues to fall for some time, unless counteracted by special treatment, as was demonstrated in a recent investigation on carbon dioxide, suggested by, and in cooperation with, Prof. Yandell Henderson and his staff, of Yale University, the report of which will be published in another paper.

Ether and chloroform lower the patient's resistance against infection—not an insignificant effect when the total of infections that follow confinement is considered, and not just simply puerperal infection.

Probably the most serious objection to the use of ether and chloroform is that they delay the progress of labor by decreasing the contractile power of the uterus, if they are given in such amount as to relieve the patient to any extent.

The fleeting character of the anesthetic properties of nitrous oxide makes it especially adaptable for obstetrical conditions. It requires only a few inhalations to relieve the patient, and only a few exhalations to remove the gas entirely from the patient's system. Even in an administration covering several hours the patient is actually inhaling nitrous oxide only a small fraction of the time, and the patient should be conscious *all* of the time, that is until, at least, the head is passing over the perineum. It is the analgesia, and not the anesthesia, that is desired to relieve the pain of the contractions, and nitrous oxide does this without interfering with the contractile force. The analgesic state, that is, where the patient is relieved of pain but is still conscious, is reached just before unconsciousness and anesthesia. With such a quickly acting agent this may seem a fine distinction, but with a little experience the distinction is readily made in practice.

The chief point in the technique of nitrous oxide analgesia is to begin the administration at the first indication of a uterine contraction, so that the patient may inhale sufficient of the gas before the maximum of the contraction is reached, and thus prevent actual pain from being experienced, and then discontinue the administration before unconsciousness is produced. In some patients two or three inhalations of nitrous oxide are sufficient to ward off the pain of a contraction, while in other patients six or eight inhalations are needed. At the end of the required number of inhalations the patient should be instructed to hold her breath as long as possible, and to bear down. Securing the cooperation of the patient in this way materially shortens the period of labor, as nitrous oxide so administered does not retard the expulsive effort; and herein lies the great difference between the results of nitrous oxide and those of ether or chloroform in this phase of obstetrical practice, as both ether and chloroform decidedly decrease the force and frequency of the

*Read before the West Side Clinical Society, New York City, October 9, 1919.

contractions, and thereby, of course, prolong the period of labor.

Let it be distinctly emphasized that until the head is passing over the perineum it is a state of analgesia, and not of anesthesia, that is desired during the contractions. That is, consciousness should be maintained throughout, with pain assuaged or obliterated. Loss of consciousness, of course, destroys the cooperative effort of the patient, and the conscious cooperation is a great factor in shortening the period of labor.

Nitrous oxide analgesia should be instituted as soon as the contractions produce a decided pain. This will vary considerably with different patients. With primiparæ when "four-finger" dilatation is reached, the pain is usually pretty acute, while multiparæ usually do not have much pain till after considerable more dilatation has occurred. The object of the analgesia is to relieve pain, so unnecessary suffering should not be allowed before instituting it. On the other hand, the administration should not be begun until the patient, on account of the pain she experiences with the contractions, is willing and anxious to cooperate in obtaining relief and in assisting the expulsive effort. Considerable patience is sometimes required to get proper team work instituted, and without the cooperation of the patient this intermittent administration for each individual pain cannot be made a success. As the labor progresses and, of course, as the pain becomes more severe, there is an increasing tendency for the patient to cooperate.

When the head is passing over the perineum, many obstetricians prefer to have their patients anesthetized, and some prefer to have them at this time rather deeply anesthetized. This can be done by adding ether to the nitrous oxide, or by giving straight ether. The response of the patient, as well as the requirements of the obstetrician, determine how the administration should be conducted at this stage, and the same applies to the administration of the anesthetic for the repair of the lacerations, if there be any, nitrous oxide, of course, being the preferred anesthetic.

Conserving the patient's vitality is another very important benefit of nitrous oxide analgesia. Many patients, especially primiparæ, are so exhausted by their suffering that before the end of labor they are physically unable to cooperate in the expulsive effort, and this at the very time when cooperation renders the maximum benefit. Not only does this unnecessary exhaustion of the patient delay the progress of labor, but often necessitates the use of forceps which otherwise would not be required. The exhausted parturient patient is also much more liable to hemorrhage, infection, and the latent ills to which she may be subject, than is the one whose vitality is conserved by the prevention of her suffering. With the patient's vitality so conserved, there follows, of course, a more rapid convalescence. In other words, nitrous oxide analgesia, in a measure, is life insurance.

Apparatus for the administration of nitrous oxide varies about as much as styles of dress. I prefer and use a very simple design. Elaborateness does not establish efficiency. Many of the different kinds of apparatus on the market were designed for use in general surgery, where a continuous administration is desired, and so they are not well adapted for the brief, intermittent administrations in obstetrical analgesia. Little oxygen is required for the majority of patients until the stage is reached where a continuous analgesia or anesthesia is indicated, that is, when the head is passing over the perineum. Cyanosis, however, should not be permitted at any stage. Oxygen and air are the antidotes, and the latter is always available. Analgesia is usually produced before cyanosis develops.

What are the comparative effects of the different anesthetics on the baby? In the brief, intermittent administrations of nitrous oxide as herein outlined, very little nitrous oxide reaches the baby, for its administration is not begun until uterine contraction has commenced, and its administration is discontinued before the contraction ceases. Spontaneous respiration in the baby appears to be as quickly and as easily established after intermittent nitrous oxide analgesia as when no anesthetic is administered. Ether and chloroform, on the other hand, are a distinct deterrent to spontaneous respiration, as is generally observed. The length of time over which nitrous oxide analgesia is maintained does not affect the spontaneity of the baby's respiration. The longest period for which I have maintained nitrous oxide analgesia is nine hours, with several other cases nearly as long. Yet in these prolonged administrations there was no difficulty in establishing the baby's respiration.

"The proof of the pudding is in the eating," is an adage to which most all will subscribe. That is the kind of proof the mothers and babies offer concerning nitrous oxide analgesia. Let me reiterate briefly the salient points: Freedom from pain of any consequence, vitality conserved, no extra toxic burden on the already overburdened organs of elimination, period of labor shortened, resistance unimpaired, more rapid convalescence, spontaneous respiration of the baby. This is not an *ideal* picture, but a *real* picture. Is it, then, too much to claim that nitrous oxide analgesia is the greatest contribution to obstetrics that has been made in the present decade?

Bretton Hall, Eighty-sixth Street and Broadway.

WILLEMS' METHOD OF ACTIVE MOBILIZATION IN SURGICAL JOINTS.*

By E. B. MUMFORD, M.D.,

INDIANAPOLIS, IND.

VISITING ORTHOPEDIC SURGEON AND CHIEF OF FRACTURE SERVICE, CITY HOSPITAL.

THE vast amount of clinical material afforded by the World War made possible the completion of many pieces of research work and the development of many new ideas in the treatment of medical and surgical conditions. In the surgical field, the work of Carrel and Dakin on wound disinfection, the new and radical procedure in chest surgery, and the treatment of shock by blood transfusion and gum injections have all been written of so often that the principles involved are common knowledge.

*Read at the meeting of the Ohio Valley Medical Association at Evansville, Indiana, November 12, 1919.

Along with these and many other notable advancements stands the work of the Belgian surgeon, Willems, a work which has been accepted by the French and by the English and which will cause to be rewritten all the chapters on joint surgery.

It is unnecessary to review the old teachings of the treatment of surgical joints, teachings which had become so dogmatic that they varied but little in the many treatises on surgery. It will suffice to recall that the principles were free drainage, drains, frequent irrigations, fixation for an indefinite period to be followed later by passive motions, massage, and baking. The end results of this form of treatment are also equally as well known to the surgeon, especially in cases of purulent arthritis and intraarticular fractures. The most hopeful prognosis that one could give was a limitation of motion in the joint while the surgeon keenly realized that even more serious things might happen. The treatment as conceived by Willems will, no doubt, at first appear as most radical in the face of our former teachings but to those who have been so fortunate as to have seen the end results of joint injuries as treated in Willems' hospital and to have had the opportunity to apply these same principles in one's own work, the skepticism and doubt are entirely removed.

The Willems treatment of surgical joints is *immediate, continuous, active mobilization.* This phrase is to be translated in the most literal sense. By *immediate* mobilization is meant that the joint shall be moved as soon as the patient has awakened from the anesthesia. By *continuous* mobilization is meant that the joint shall be moved as often as the muscle power of the patient will permit. By *active* mobilization is meant that all motions shall be made by the muscles which control that particular joint; that at no time shall the nurse or the surgeon or the patient use in any way passive motion.

Prior to the war, Willems had used with success his treatment in the simple traumatic effusions of the knee. The great variety of joint lesions as a result of war injuries gave him an opportunity to extend his treatment to the more serious type of joint wounds and thus to prove the soundness and the practicability of his theories. It is not the purpose of this paper to describe in detail the treatment of each of the different joint conditions, but to outline the general principles which underlie the method as it applies to all conditions, leaving to the surgeon modifications which will readily suggest themselves. In the purulent arthritis the best results have been obtained in the knee and in the elbow cases.

It is important to remember that Willems' treatment is applicable only in acute conditions. After firm adhesions have been formed in the joint cavity, changes in the periarticular tissues have developed and atrophy of the muscles has taken place Willems' treatment has no value. Many have failed to obtain results with this method and have condemned it because they have overlooked this point and have tried to apply the principles to the old chronic cases. This was especially true in England, where the cases were received late from the front line hospitals. Willems was especially fortunate in that his hospital was situated within a few miles of the front line and he could also keep his patients as long as he desired. This made possible his receiving his patients immediately after they had been wounded and also gave him an opportunity to see the end results of his work.

In order to present in detail the principles of Willems, a knee type of purulent arthritis will be used. The knee is prepared as in a clean case, the author preferring the iodine preparation of the skin. Before opening the joint aspiration should be done in order to determine the character of the fluid. Frequently, a hemarthrosis will present all of the symptoms and signs of a purulent fluid and, of course, should not be opened unless infected. If there has been a small puncture wound the tract should be carefully located by a small probe that the tract may be fully excised later. If pus is found in the joint, a long longitudinal incision should be made on the outer side of the knee. It is important to carry this incision well up the thigh to the top of the bursa which lies beneath the quadriceps femoris tendon as this bursa is a part of the joint cavity and must be drained. In most of the cases a single arthrotomy will give sufficient drainage but should an incision be necessary on the inner side of the knee, care should be used to damage as little as possible the important internal lateral ligaments. The U-shaped incision involving the patellar ligaments will rarely if ever be required to give perfect drainage. Unless there is some foreign material present in the joint, irrigation of the joint cavity is not done. Drains are not used either in or to the joint. The dressing consists of large quantities of plain dry sterile gauze so placed that motion at the joint level will be free. Antiseptic solutions are not used and the dressing is changed only as it becomes soiled.

As soon as the patient has awakened from anesthesia the active mobilization is begun. It is during the next forty-eight hours that the most important phase of the treatment is developed. In order to give a satisfactory end result and to carry out the schedule of the active mobilization, it is absolutely essential that the cooperation of the patient be obtained as he alone will have all of the work to do. In order to gain his co-operation the patient must from the first have confidence in himself and in his ability to move the joint. Unless the surgeon is willing to give the time necessary to obtain these two important factors, he cannot expect results other than he would have had with fixation, irrigations, and drains. If possible a special nurse should be on every case for at least four days in order to see that the orders of the surgeon are carried out by the patient.

At first the patient is required to bend the knee but slightly, the heel resting upon the bed. This will demonstrate to the patient that it is not only possible for him to move the knee but that the motion is not extremely painful. This will also make him understand that he will at all times have full control of the situation in that neither the surgeon nor the nurse will touch the leg. As soon as these two points are made, the patient then locks his hands behind the thigh and lifts the leg into the air with flexion at the hip and holding the knee fully extended. With the leg in this position, he is then urged to bend the knee and then bring it back into extension by the action of the quadriceps. At

first this flexion movement will be slight but is gradually increased in its arc until a considerable degree of flexion is obtained.

In order that the active mobilization be carried out, it is best to have a regular schedule. In Willems' clinic the motions were made every hour until the muscles were fatigued, the patient, however, not being disturbed during the night. In De Page's clinic at La Panne, Belgium, a two-hour schedule was maintained both during the day and the night. The active mobilization is continued until the arthrotomy wounds are healed and the patient is able to leave the hospital without the use of cane or crutches.

The pain which is occasioned by the active mobilization is during the first few days rather severe, but not of the unbearable type which characterizes an acutely inflamed joint nor that which comes later in the use of passive motions. Inasmuch as the patient has full control of the situation he is more willing to bear the pain and especially so as he finds that it is less each day. At the end of the third day, the pain is a negligible factor.

At the end of the fourth or fifth day the patient may be allowed to take a few steps and there is nothing more striking than to see the patient walking about the dressing room with the pus pouring from the open knee joint and running down the leg. In one case on my service at De Page's hospital the pus would be expelled in spurts at each motion of the joint.

Fever is not a contraindication to active mobilization in purulent arthritis. If the drainage is good, the temperature falls rapidly to 99° or 99.5°, and any long continued high elevation of the temperature will indicate the pocketing of pus, the most common place being in the bursa beneath the quadriceps femoris tendon or an extension up the fascial planes of the thigh.

In intraarticular fractures the same principles of treatment will apply, providing the active mobilization does not disturb the fragments to a considerable degree. In compound fractures into the joint, it is advisable to enlarge the wound, excising all devitalized tissue and removing all foreign material. The joint is then washed with ether and the capsule closed tight with catgut sutures. It has been shown most conclusively that the joint can take care of slight infections as well as can the peritoneum or pleura and that the tragic end results of entering the joint cavity are not the result so much of the opening of the capsule as of not closing it tightly.

If any small pieces of bone are found lying free in the joint cavity, they should be removed and after the wound has been closed tightly, active mobilization should be begun at once. In Willems' clinic I saw some cases in which one entire condyle of the femur had been removed and the patient had as an end result 75 per cent. of motion in the knee joint, a lateral iron being used to prevent a lateral bending of the knee.

The principles of the treatment of surgical joints as outlined by Willems are, though they may not be entirely new, most radical compared with our former conceptions in the cases. However, they have been given a most thorough investigation and in the hands of many other men have given the same gratifying results as are obtained by Willems. The advantages of this method of joint treatment may briefly be summarized thus:

1. Adhesions of a serious nature are reduced to the minimum. One of the most striking observations during the treatment is to watch the open knee joint during motion and to see the breaking through of the soft fibrous adhesions which had formed during the interval of rest.

2. The most thorough drainage of the joint cavity and the pockets of pus is given through the active mobilization, as at each movement the shape of the cavities is changed and the pus is expressed. Popliteal space involvement is thus less apt to occur.

3. Atrophy of the muscles is prevented. This is one of the most important phases of the treatment. The tone of the muscle is retained in a way that it cannot be through simple massage and hot applications.

4. The retrogressive changes in the highly specialized tissues of the joint and the muscle and tendon tissues, which come through disuse, are also eliminated. This factor should be emphasized as it is not generally recognized by the surgeon and is one of the most common causes for the stiffness in joints which follows long fixation.

5. With the simple dry dressings the pain which comes through drains and irrigations is prevented. This is an important factor in regard to the comfort and to the general physical condition of the patient.

408 Hume-Mansur Building.

Medicolegal Notes.

Expert Testimony as to Cause of Condition.—The New York Appellate Division holds that it was improper, in a personal injury action, to permit the attending physician to testify that the plaintiff's condition of edema of the legs was not due to other cause than the accident; that question being for the jury. An objection to the question, on the ground that it was improper in form and called for incompetent testimony, was held sufficiently specific to call the court's action to the fact that it was the form of the question that was being objected to.—Broderick v. Brooklyn, Q. C. & S. R. Co., 174 N. Y. Supp. 571.

Proof of Cause of Hernia.—The Kentucky Court of Appeals holds that proof that the insured was suffering from a hernia about as large as an egg one day, and that on the following day it had developed to the size of a half-gallon cup, causing loss of time, was insufficient to show that the enlargement was caused by external, violent, and accidental means within an accident policy; although a case might arise where the character of the injury was such that it could not have been caused in any other way than by external, violent, and accidental means.—Transylvania Ins. Co. v. Allen (Ky.) 209 S. W. 44.

Husband's Liability for Medical Services to Wife.—The Georgia Court of Appeals holds that upon the trial of an action against a husband for medical services rendered by the plaintiff to the defendant's wife, evidence that before the date of the services by the plaintiff the defendant left the state as a fugitive from justice, taking his wife with him, and that she later returned to the former community and lived upon land belonging to her husband, the husband still remaining away, does not necessarily demand the inference that the parties were living in a state of separation as husband and wife under such circumstances that the husband would not be liable for necessaries, such as medical services furnished by the plaintiff to the wife.—Ward v. Johnson (Ga.), 8 S. E. 405.

THE DIAGNOSIS OF SYPHILITIC SUBOCCIPITAL POTT'S DISEASE.

GIVEN the extreme infrequency of syphilitic suboccipital Pott's disease, when compared with tuberculosis or certain forms of rheumatism in this region, it is evident that its diagnosis offers much difficulty. However, the relatively advanced age of the patient, the specific antecedents and evidences of luetic stigmata, should lead the clinician to suspect a suboccipital syphilitic process when certain symptoms are accentuated, such as spontaneous painful stiffness of the neck from the onset, made worse by rest in bed, a sharp pain on pressure over the spinous apophyses of the first cervical vertebræ or over the upper part of the pharynx, with a satisfactory general physical condition. A positive Wassermann would, of course, be in favor of the specific nature of the process. An important sign of suboccipital localization of syphilis is that the patient supports his head in his hands. Radiography will reveal the site and extent of the lesions.

The differential diagnosis must be made from traumatic lesions, but above all from chronic rheumatism or gonorrheal infections, spondylosis, and especially tuberculosis. In some cases syphilitic suboccipital Pott's disease has been complicated by fracture or subluxation, when, on palpation, a vertebra projecting into the pharynx will be detected.

Torticollis does not give rise to localized pain over the vertebræ, while the lateral inclination of the head in no way resembles suboccipital disease in which the head is in hyperextension or hyperflexion.

Gonorrheal rheumatism has a rather sudden onset and there is a more decided febrile movement than in the process under consideration, and it does not give rise to localized pain in the cervical vertebræ. In spondylosis the stiffness is usually generalized, and the patient walks as if made of a single piece.

The differential diagnosis between syphilitic and tuberculous suboccipital Pott's disease is delicate, but the tuberculous syndrome is quite different from the luetic. In the tuberculous subject there will be the history of scrofula, enlarged lymph nodes, and repeated attacks of bronchitis. The tuberculous subject can be quite readily distinguished from the syphilitic. The latter is usually an adult in fairly good physical condition, the former will be a puny child in bad physical condition, offering at the same time evidences of pulmonary, lymphatic, or other manifestations of tuberculous infection.

The symptomatology of the suboccipital lesions is different in the two processes. In syphilis the pain is spontaneous, and worse at night and during rest, but the pain is relieved by rest in tuberculosis and is more likely to be provoked than spontaneous. Bacillary lesions frequently suppurate, sinuses form, and occasionally, but infrequently, large sequestra are eliminated. Gummata, on the contrary, give rise only to a bloody serous fluid, or to a small amount of thick pus; abscesses are rare, and quickly heal, while the sequestra are multiple and small. Antisyphilitic treatment will improve, or even cure, the process, or at all events never aggravate it, as it does tuberculosis of the bones.

Finally, the laboratory may be resorted to in doubtful cases, especially when the symptoms are not so distinctly manifest, and do not clearly indicate the nature of the process. The microscope will reveal the tubercle bacillus or the pallid spirochete, as the case may be. When positive, the Wassermann is a valuable diagnostic aid. The intradermic reaction, if negative in a subject suspected of syphilis, will confirm the diagnosis, especially when the Wassermann is positive.

VENEREAL DISEASES IN THE ANTENATAL PERIOD.

GONORRHEA and syphilis during pregnancy are of grave import to both child and mother. Of these syphilis is the more dangerous and the greater menace. Gonorrhea is more dangerous by far to the mother than to the child. In fact almost the only risk that the child runs from a case of gonorrhea in the mother is eye infection. On the other hand, infection with the disease during pregnancy is serious because of the danger of extension of the infection to the tubes, ovaries, and peritoneum. Dr. Mary Raw writing on the subject in the *Journal of the Royal Sanitary Institute* November, 1919, points out that it was the opinion of several authorities who gave evidence before the Royal Commission on Venereal Diseases, that "somewhere about 25 per cent. of all the serious inflammations and abscesses which may affect the internal generative organs of women are due to gonorrhea." Gonorrhea is serious because of the danger of sterility, but syphilis is of the greatest importance from the antenatal standpoint. Dr. Amand Routh says that "in urban districts 25 per cent. of the total antenatal deaths and deaths during the first month after birth, are due to syphilitic infection of the fertilized ovum or fetus, and that probably 20 per cent. would be a fair percentage over the whole of England and Wales. This would mean that about twenty-seven thousand deaths would occur annually in England and

Wales during the ante-natal period and first month of life."

Dr. Raw classes pregnant women suffering from syphilis as follows: (1) Those who have definite clinical signs such as chancre, rash, or other local manifestation. (2) Those who present no obvious signs of the disease, but who have a history of miscarriages, still births, or premature births. In regard to diagnosis in these cases careful questioning will sometimes elicit particulars of a previous illness, or local lesions that are very suggestive. In many cases, however, no such data can be obtained. As for treatment Dr. Raw holds that there is no reason why, if care is exercised, a course of treatment with arsphenamine and mercury should not be given to pregnant women. Special attention should be paid throughout the course to seeing that the drugs are being well borne, the danger of miscarriage from toxic causes being kept in mind. If these patients come under treatment early in their pregnancy, there is time for a sufficient course to be given to warrant the hope that a healthy child may be born.

INTERNAL REMEDIES IN PSORIASIS.

THE vexatious subject of the treatment of psoriasis is discussed by the distinguished dermatologist Sabouraud in *La Presse Médicale* for January 21, 1920, xxviii, 6. The disease probably never undergoes spontaneous recovery, and it is generally regarded as incurable. Benign cases apparently yield to treatment, but this is often the result of an illusion, for the nature of these cases is to present periods of latency; they may improve under local treatment, but recurrence sooner or later apparently is inevitable. The results obtained are hardly worth the trouble taken. The author does not include diet under internal treatment; it is, of course, admitted that under certain severe regimen relapses may be warded off for prolonged intervals, but it has not been satisfactorily proven that regimen can really cure the disease. From another viewpoint there is no known factor which can aggravate the disease, for if there were it might give us a line on successful treatment.

When a psoriatic contracts syphilis it has been noted with surprise that the specific treatment will clear up the skin of syphilides, psoriasis, and all. This hint has been utilized, and some cases of psoriasis in non-syphilitics have cleared up under calomel injections while others have not. This fact seems to hold good for all antisyphilitic remedies, and Danlos has reported some quite remarkable results from the use of cacodylate of sodium, but the more powerful arsenicals like salvarsan apparently hold out no real hope. The author notes that intercurrent typhoid fever has cleared up a psoriasis, with reappearance during convalescence, but he does not mention the apparent cures obtained by the injection of anti-typhoid vaccine. Bory believes that in colloidal sulphur he has found an antipsoriatic of merit, but Sabouraud believes the results to be inferior to those obtained by arsenicals. He does not mention the ordinary use of Fowler's solution or of arsenical mineral waters, but the well-known sulphur springs have some repute in this direction. The *x*-rays applied to one extremity may clear up the spots, and recently Danyzs has applied an autogenous vaccine made from the patient's intestinal microorganisms with alleged benefit. Sabouraud has studied the results of this treatment, but is not enthusiastic over the resource as a routine procedure, although he concedes that it may have power over the disease when used persistently for a long period.

In this country some quite remarkable results—only time will enable us to pronounce them cures—have been obtained by the injection of antityphoid vaccine and nonspecific proteins, especially those derived from vegetable seeds and grasses, the so-called proteals. Sabouraud appears not to have heard of this method, but it is well worth his study.

MEDICAL HISTORY.

POSSIBLY, if we search long enough, we may succeed in finding a medical school which gives a place in its curriculum to medical history. The place is necessarily small, for goodness knows it is hard enough to get present-day medical facts before the students, let alone the humors and boiling oil of the ancients. Still, it is at least a recognition of the value and interest of the subject even in these hard-pressing times. The subject is of great and really vital importance, and that it is interesting to a fascinating degree no one will deny. Moreover, to the majority of medical men it is absolutely unexplored ground. Lawyers may know their Roman law or any other part of legal history; ministers may know church history backward, but the average doctor could not tell you any more about Hippocrates than that he wrote an oath; nor about Galen than that some veins were named for him. A few remarks about history prefacing the text-book discussions of the various diseases—and there you are! The result is that our graduates in medicine miss much which is of real charm and cultural value, and by no manner of means devoid of utilitarianism. Witness the various "discoveries" heralded from time to time, which are found, after a little research into the records of the past, to be merely reincarnation of long-dead theories.

At present, undoubtedly the best way to get medical history before the undergraduates is to offer them a course of, say, six lectures designed to awaken their interest in the subject, and acquainting them with the most readable medical histories. Then those sufficiently interested among both faculty and students could make good use of a club, like the Charaka, for instance, at whose meetings papers would be read by members or guests on medical-historical subjects. A few such clubs have been formed, and they have proved to be of great value. The establishment of a Section of Historical Medicine of the New York Academy of Medicine is an

important advance in this direction, and its work will undoubtedly stimulate research in medical history. Certainly, chairs of a history of medicine are needed in our schools to-day. The makers of the profession's strenuous present should not forget the makers of its fruitful past.

Clinical Research.

To the vanishing element of the medical profession which may be said to belong to the "old school"—those who exercise that power, intuitive and unteachable but capable of development, which the late Dr. Emil Gruening was wont to call the "*imponderabilia*"—the establishment of the St. Andrews Institute for Clinical Research comes in the nature of a vindication. This element has long known that instrumental methods of diagnosis alone are insufficient in a large proportion of cases of a goodly number of diseases. To this class belongs the physician who, for example, having been accustomed to study minutely the symptomatology of disease, recognizes typhoid fever and is well along with its treatment before the instrumental diagnostician delivers his pronouncement. It may be vouchsafed, too, that many a "new school" practitioner of medicine of more or less philosophical trend of mind has often felt the need of something more than the modern diagnostic laboratory to aid him in the quick recognition of disease. Both the old and the new schools of medicine, therefore, may watch with interest the development of the new institution whose aim is the prevention of disease through a study of its clinical manifestations first. Sir James Mackenzie, founder and director, formally opened the Institute with a masterly address on clinical research, which is published in full in the *British Medical Journal* and abstracted in this issue of the Medical Record.

Encephalitis Lethargica Diagnosticated as Cerebral Influenza.

Although many, especially in England, think that sleeping sickness is much more closely related to infantile paralysis than to influenza the idea that the affection may be grippal will not down, especially among those acquainted with the history of former epidemics. A case which was originally reported in an Argentine journal and is found in abstract in *El Siglo Médico* for January 7, 1920, lxvi, 3445, occurred in a woman of 22 with negative antecedents who was two months pregnant. She was seized with headache and fever and suddenly bilateral ptosis supervened. There was quiet delirium with somnolence. The latter symptom was early and continuous, and before taking to her bed the young woman was continuously dozing in her chair. She conversed at times and spoke distinctly. As she was gravid the scanty urine was at once examined and proved to be normal. However, renal complications were feared and energetic derivative treatment was practised. The only response was that abortion occurred, but there was no resulting improvement in her condition. To the ptosis was added some internal strabismus. Inspection of the mouth revealed the socalled "grippal arch" on the palate with mild pharyngitis. The "porcelain tongue" of Faissans was in evidence and the conjunctivæ was suffused. Uremia and meningitis were now definitely excluded. Another affection excluded was botulism, as were also cerebral syphilis and abscess and tumor of the brain. There was no examination of the cerebrospinal fluid. After twenty-eight days of somnolence the patient suddenly expired. Clinically the case was lethargic encephalitis. Influenza was epidemic at the time in the vicinity, and there was absolutely no other causal factor to invoke.

A Symptom of Hyperthyroidism.

Dr. Maranon of Madrid has described in the *Revista Española de Medicina y Cirugia* for November, 1919, ii, 17, an induced symptom which he found present in 92 out of 100 cases of hyperthyroidism, irrespective of the clinical type of the latter. By slightly rubbing or pressing with the fingers the integument of the throat an intense vasomotor reaction may be provoked. It is not confined to the area rubbed but may extend to the anterior wall of the thorax. In goitrous subjects the distribution is markedly influenced by the area of the goiter, whether unilateral or bilateral. The red area may be continuous or dissociated, and in certain cases an urticarial component is evident, the area showing slight elevation. The mere fact that the practitioner is about to compress or stroke the skin may cause the phenomenon without actual contact. A blush may appear independently on the thorax or other distant point. A proportional or quantitative behavior has not been seen, and the vasomotor irritability is quite independent of the degree of hyperthyroidism in a given case. The author claims a certain priority in calling attention to this symptom, although Chvostek has called attention to the unmotivated blushing of the hyperthyroid subject. The author belives that excess of thyroid or altered thyroid secretion has sensitized the vasomotor apparatus and he would place the phenomenon under sympathicotonic (?) manifestations. It is seen predominantly in women, in the young and at the menopause. The author is silent as to any possible relationship to dermographism.

News of the Week.

Health of the Troops.—The following report of disease among troops is given by the *Army and Navy Journal* of February 21: Influenza continues at many of the large camps and stations, principally among the eastern and southern stations, having decreased in the camps and stations located in the central part of the United States where the present epidemic first appeared. Although there were fewer new cases of influenza reported during the week ending Feb. 16, the number of new cases of pneumonia is double the number reported the previous week. The admission and non-effective rates show a slight decline while the death rate is more than double that of the previous week, due to seventy-two deaths from pneumonia and six from influenza against thirty-three from pneumonia and one from influenza in the week of Jan. 30. Special

diseases were reported as follows: Influenza, 1347; pneumonia, 211; measles, 33; meningitis, 1; malaria, 5; scarlet fever, 7; diphtheria, 7. There is a marked decline in the number of new cases of influenza, measles and pneumonia among the American Forces in Germany and a corresponding increase in the death rate for disease. There were only two deaths from disease reported this week against five in the previous week. Among the American Forces in Siberia influenza shows a slight increase, but there is a decrease in the number of pneumonia and measles. No deaths were reported among these troops for the week.

Examination for Scientific Aid. — The United States Civil Service Commission announces an open competitive examination to be held March 16 for scientific aid in the Division of Anthropology, National Museum, Washington, D. C. The salary is $1,500 per year. Both men and women are eligible. Applicants should at once apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C.; the Secretary of the United States Civil Service Board, Customhouse, Boston, Mass., New York, N. Y., New Orleans, La., Honolulu, Hawaii; Post Office, Philadelphia, Pa., Atlanta, Ga., Cincinnati, Ohio, Chicago, Ill., St. Paul, Minn., Seattle, Wash., San Francisco, Calif.; Old Customhouse, St. Louis, Mo.; Administration Building, Balboa Heights, Canal Zone; or to the Chairman of the Porto Rican Civil Service Commission, San Juan, P. R. Applications should be properly executed, including the medical certificate, and must be filed with the Civil Service Commission, Washington, D. C., prior to the hour fo closing business on March 16, 1920.

Ophthalmic Examinations. — The American Board of Ophthalmic Examinations will hold an examination at New Orleans, April 26, at the time of the meeting of the American Medical Association. Candidates who wish to take the examination for the certificate of the board must have their application and the necessary credentials in the hands of the secretary, Dr. William H. Wilder, 25 East Washington Street, Chicago, at least sixty days before the date of examination. The three chief functions of the board, which was organized in 1916 by committees from the American Ophthalmological Society, the Section on Ophthalmology of the American Medical Association, and the American Academy of Ophthalmology and Oto-Laryngology, are: *First.* To establish standards of fitness to practice Ophthalmology. *Second.* To investigate and prepare lists of medical schools, hospitals, and private instructors recognized as competent to give the required instruction in Ophthalmology. *Third.* To arrange, control, and conduct examinations to test the qualifications of those who desire to practice Ophthalmology, and to confer a certificate upon those who meet the established standards.

Warning Against Ripe Olives.—Federal and State food inspectors in fifty-two towns of eight States are said to be making an effort to locate and destroy dozens of bottles of ripe stuffed olives containing the *Bacillus botulinus*. The brands involved are "Batavia," "Ferndell," and "Richelieu." Only ripe olives, stuffed with pimentoes and sold in bottles are said to be affected. New York State: Richelieu Brand—Auburn, 12; Utica, 2; Malone, 3; Geneva, 10; Gloversville, 3; Ferndell Brand—Syracuse, 12; Oneonta, 6; Lockport, 12. Indiana—Richelieu Brand—Monticello, 4; Ferndell Brand—Fort Wayne, 12; Batavia Brand—Indianapolis, 6.

Ten Thousand Defectives at Large in New Jersey.—The State Board of Institutions and Agencies of New Jersey has submitted a report to Governor Edwards and the joint legislative appropriations committee stating that there are approximately 10,000 feeble-minded, epileptic, insane, unstable, and "unadjusted" persons and incipient and advanced tuberculosis patients at large in the state and unprovided for. The board asks that $2,500,000 be provided for 1920 and $1,500,000 for each year thereafter until 1931, for a construction program giving adequate facilities for caring for such persons.

Expansion of State Health Department.—In a message to the New York State Legislature on February 17, accompanying the report of the Reconstruction Commission on Public Health, Governor Smith reiterated his strong advocacy of a broad public health policy and urged that the state assume greater responsibility. He suggested that the state should subsidize local health affairs and co-ordinate private and public health facilities, and urged liberal financial provision for the Department of Health.

Rabies Dormant Two Years.—A negro in Alabama is alleged to have developed rabies two years after he was bitten by a pet dog. He was sent to a hospital in Montgomery, where he attacked the nurses and other attendants. In attempts to subdue him he was shot and killed by officers.

Influenza in Germany. — According to press dispatches under date of February 15 the epidemic of influenza in Germany has spread alarmingly. The number of cases in Berlin had risen to over 700 daily, and during the week there were about 100 deaths in the city's hospitals. The epidemic had spread to many places west of Berlin. At Dortmund, where it was most severe, there were 115 deaths during the week, the victims being either children from one to ten years of age or persons between thirty and forty years of age. In the majority of cases the disease is accompanied by pleurisy.

Food Cards in Italy.—The card system for the necessaries of life has been re-established in Italy under the same conditions as during the war. Bread, rice, maccaroni, coal, lard and fats are issued by card. This has been rendered necessary by high rate of exchange, the difficulty of obtaining transport, and the scarcity in supplies.

German Children and the War. — Professor Abderhalden of Halle is reported as having declared that but for the war 2,000,000 children would have been born in Germany between 1914 and 1918. Half a million children were suffering from starvation at the time of the armistice, over 100,000 of whom would have died but for steps then taken. Tuberculosis and rickets were prevalent to a terrible degree among the youth of Germany. Contrary to all reports, declared the professor, food conditions were better in Vienna than in Germany.

Work for British Disabled Soldiers.—It is reported that since the national scheme for employment of disabled men was started in Great Britain last September, 9500 firms have agreed to employ a stated percentage of disabled men. The quota is generally 5 per cent. Employment has been guaranteed for 97,000. There are still 40,000 disabled men waiting for work, and the hospitals have many more to discharge.

Esthonian Relief Work Halted.—Typhus and influenza, which are raging among the remnants of the Yudenitch anti-Bolshevik army in Esthonia, have caused the collapse of the Russian relief organizations caring for the refugees in that country, according to news received by the American Central Committee for Russian Relief in New York. About $10,000,000 are available for the work for the next five months, but the Esthonians, faced with caring for their own people, are unable to take over the relief work of the Russians. The only agencies operating in the country are temporary civilian organizations. Of the 28,000 refugees who are being fed, 16,000 are said to be ill, most of them suffering from typhus fever.

Woman Trustee of Bellevue Hospital. — Mrs. Benjamin Lissberger has been appointed by Mayor Hylan of New York City as a member of the board of trustees of Bellevue Hospital to serve for a term of seven years. This is the first time in the history of the institution that a woman has served in this capacity.

Association of American Peroral Endoscopists.—The next meeting of this association will be held in Boston on June 1, under the presidency of Dr. John M. Murphy of Cincinnati. The secretary is Dr. Samuel Iglauer, 701 Race Street, Cincinnati.

Dr. Stephen Smith of New York City celebrated his ninety-seventh birthday February 20 en route to California. Dr. Smith was born on a farm near Skaneateles, N. Y., in 1823, coming to the city when he was a young man. He has long been the dean of the New York medical profession.

Dr. Mabel Ulrich of Minneapolis, Minn., has been appointed director of health service for the American Red Cross in Minnesota, North and South Dakota and Montana. Her principal task will be to coordinate the work of the various committes, agencies and organizations engaged in public health work in the territory to which she is assigned.

Forty Thousand Cripples in New York City.—The Committee on Survey of Cripples has been listing the cripples in New York City, with a view to determining whether these individuals are being properly looked after medically, educationally, and industrially. It has been found that the average ratio of cripples to total population is 7 to 1,000, or more than 40,000 on a population basis of 6,000,000. More than half of the cripples are under 15 years of age. It was found that in a district of sixteen blocks in Greenwich Village, whose population as estimated by the canvassers is 18,609, there are 178 cripples, only ninety-two of whom are being treated. On the East Side ten blocks showed a population of 20,503, with ninety-three cripples, forty-nine being under treatment. In Harlem the same number of blocks gave a population of 13,364, with 134 cripples, seventy-three being treated. The Red Hook district of Brooklyn showed a population of 15,690 living in seventeen blocks, with eighty-four cripples. Twenty-four blocks in the Bronx with a population of 22,002 had 121 cripples, fifty-seven of whom were being treated, and fourteen blocks in Williamsburg with 15,066 population had 130 cripples. The majority of the cases not being treated are neglected because there is no agency to search them out. This committee, of which Thomas S. McLane is chairman and Henry C. Wright director, represents forty-one hospitals and associations dealing with cripples. The other members of the committee, of whom the first five, together with the chairman, constitute an executive committee are: Dr. Thomas J. Riley, representing the Brooklyn Nursing Agencies; Dr. S. S. Goldwater, the General Hospitals of New York; Douglas MacMurtrie, the Federation of Associations for Cripples; Dr. E. H. Lewinski-Corwin, the Out Patient Hospital; Alexander M. White, treasurer of the committee; James H. Perkins, representing business interests; William Church Osborn, philanthropy in general; Mrs. Henry B. Barnes, nursing agencies; Mrs. John S. Sheppard, hospital social service; Dr. Virgil P. Gibney, orthopedic hospitals of Manhattan; Dr. Jacques Rushmore, orthopedic hospitals of Brooklyn; Dr. Andrew W. Edson, Board of Education.

Influenza Epidemic in New York City Officially Ended.—Commissioner Copeland of the New York City Board of Health has declared the epidemic of influenza officially at an end. Orders relating to closing hours and other restrictions have been withdrawn.

Children's Hospitals in Lille.—An appeal has been made to Americans to contribute to the fund being raised for the Children's Hospitals in Lille, France. It is estimated that the rebuilding of the city will require at least two years, and during that time the inhabitants will be unable to support the hospitals. Checks may be sent to W. R. Grace & Co., Hanover Square, New York City.

Doctors' Service Corps Organized.—According to recent announcement, a group of physicians, surgeons and dentists who served in the Army and Navy during the World War have organized this national body, with headquarters in New York City. The purposes of the organization are said to be to promote public health, to relieve the doctors of the business side of their work, to combat quackery, and to advance scientific standards and professional ideals.

Results of Bulgarian Occupation of Macedonia.—The Greek government recently completed a census of the survivors of the Bulgarian occupation of Macedonia, from which it is learned that of a total population of 315,000 living in 339 villages, more than 32,000 Greeks died of hunger, assassination, and disease.

Medical Society Elections.—The MEDICAL SOCIETY OF THE COUNTY OF HERKIMER on December 3 elected the following officers for the coming year: *President*, Dr. H. H. Halliwell; *First Vice-President*, Dr. J. H. Sheffield; *Second Vice-President*, Dr. Harry W. Vickers; *Third Vice-President*, Dr. Frederic S. Cole; *Secretary*, Dr. A. Walter Suiter; *Treasurer*, Dr. George Graves.

THE NEW HAVEN (CONN.) MEDICAL SOCIETY, at its annual meeting January 21, elected the following officers for the ensuing year: *President*, Dr. Robert E. Peck; *Vice-President*, Dr. Raynham Townsend; *Recording Secretary*, Dr. Frank L. Phillips; *Financial Secretary*, Dr. Samuel J. Goldberg; *Treasurer*, Dr. Frank H. Wheeler.

THE ASSOCIATED PHYSICIANS OF LONG ISLAND, at their twenty-second annual meeting held January 31, 1920, elected the following officers for the ensuing year: *President*, Dr. Henry Goodwin Webster; *First Vice-President*, Dr. Harris A. Houghton; *Second Vice-President*, Dr. Hugh Halsey; *Third Vice-President*, Dr. Joshua M. Van Cott; *Secretary*, Dr. James Cole Hancock; *Treasurer*, Dr. Edwin S. Moore.

THE NEW BRITAIN MEDICAL ASSOCIATION, at its annual meeting January 22, elected the following officers for the coming year: *President*, Dr. W. J. Robbins; *Vice-President*, Dr. F. J. Mann; *Secretary-Treasurer*, Dr. George W. Dunn.

THE ST. CROIX (MAINE) MEDICAL SOCIETY recently elected the following officers to serve for the ensuing year: *President*, Dr. F. A. Duston; *Vice-President*, Dr. H. R. DePue; *Secretary-Treasurer*, Dr. J. W. J. Marion.

THE BERRIEN-COOK COUNTY (GEORGIA) MEDICAL SOCIETY, at its annual meeting recently held at Cordele, elected the following officers for the next year: *President*, Dr. H. W. Clements; *Vice-President*, Dr. M. L. Weeb; *Secretary-Treasurer*, Dr. M. R. Hutchinson.

Obituary Notes.—Dr. RICHARD F. BOONSTRA of the health department died of pneumonia in Detroit, Mich., January 30, at the age of 31. He was graduated from the Medical Department of the University of Michigan in 1913. During the war Dr. Boonstra was in the aviation service.

Dr. RIDGELY BROWN WARFIELD of Baltimore, Md., was found dead in bed February 4. Dr. Warfield was graduated from the University of Maryland Medical School in 1884, and for a number of years was professor of surgery in that institution. He was senior surgeon at the Maryland General Hospital. He was a fellow of the American College of Surgeons, and member of the American Medical Association.

Dr. EDWARD A. ARNOLD of East Orange, N. J., died from influenza-pneumonia February 5, in his thirty-second year. He was graduated from Cornell University Medical College in 1909.

Dr. HERBERT E. GARDINOR of New York City died suddenly on December 1, at Jerusalem, Palestine, at the age of 48. He was graduated from the College of Physicians and Surgeons in 1891.

Dr. B. HOLLY SMITH, president of the faculty of the Baltimore Dental College, was found dead in bed at his home in that city on January 22. He was 61 years of age. He was graduated from the Baltimore College of Dental Surgery in 1881, and two years later from the College of Physicians and Surgeons, New York City. He was widely known as an oral surgeon and as a teacher of this subject. He was a member of the National Association of Dental Faculties, the National Dental Association, and other organizations.

Dr. JOEL J. FOULON of East St. Louis, Ill., died of heart disease January 23, at the age of 58. He was graduated from Missouri Medical College in 1887, and had been associated with his twin brother, Dr. Z. S. Foulon, in the practice of medicine in East St. Louis for thirty years.

Dr. FRED J. BOWLES of New York City died January 28. He was graduated from New York University Medical College in 1884, and specialized in ophthalmology and oto-laryngology. He was a member of the American Medical Association, the American Academy of Ophthalmology and Otolaryngology, and other organizations.

Dr. HENRY RUDOLPH WIDMER of Newark, N. J., died suddenly January 31. He was graduated from the College of Physicians and Surgeons, New York City, in 1903.

Dr. WILLIAM E. HOWLEY of New York City died February 1. He was graduated from New York University Medical College in 1891.

Dr. CARY HAMILTON WILKINSON died at his home in Galveston, Texas, February 2, at the age of 76. He was graduated from Jefferson Medical College, Philadelphia, in 1869, and had practised in Galveston continuously since his graduation.

Dr. JOHN JASPER SEWALL of Newport, Me., died February 3, after a long illness. He was born in 1857, and was graduated from New York University Medical College in 1884.

Dr. FRANK C. HERSHEY of Carmel, Indiana, health officer for Hamilton County, died of blood poisoning February 4, at the age of 53. He was graduated from the Medical College of Indiana, Indianapolis, in 1894.

Dr. EDWARD H. LAKE of Ross, Calif., surgeon on the Union Steamship Company's liner *Tofua*, died of heart disease on board the vessel January 28, when several hundred miles from port, en route from Wellington. His body was buried at sea. He was graduated from the St. Louis College of Physicians and Surgeons in 1895.

Dr. ERNEST HENRY NOYES of Newburyport, Mass., died February 8, after a long illness. He was born in 1853, and was graduated from the Medical School of Harvard University in 1880. Dr. Noyes was a member of the American Medical Association, the Massachusetts Medical Society, and other organizations.

Dr. WILLIAM A. MYERS of Brooklyn, N. Y., died from cardiac disease February 15, in his fifty-fourth year. He had been ill since 1904, when he fell and injured his spine. Dr. Myers, who was one of the founders of the Bushwick Hospital, was graduated from the New York University Medical College in 1888.

Correspondence.

LETTER FROM GENEVA.

GENEVA, SWITZERLAND, February 5, 1920.

As in all other medical centers, the dermatological and syphilidographic clinic of the University of Geneva has given much attention to the study of the Wassermann reaction and its clinical value. But for the uninitiated, this test of the activity has its dangers and Prof. Oltramare frequently relates in his lectures that many of his former syphilitic patients come to him for a Wassermann on their own account, without troubling themselves

even to know if the data obtained can be relied upon. For them a negative result is synonymous of a cure, while the contrary means an uncured or even serious syphilis. For this reason Oltramare very rightly objects to telling patients the results of the examination because of the deplorable results that may accrue. For example, he mentions a patient formerly under his care who returned to him with the mouth garnished with mucous accidents and denied their specific nature because a few days previously a Wassermann made at Zurich had been found negative. The test was repeated at Geneva and was found very positive, while the lesions quickly disappeared under specific treatment. But this proof was necessary to convince the patient.

Many similar mistakes doubtless can be recorded and they are entirely comprehensible when the real delicacy of the technique of seroreaction is considered, and the little confidence to be given it unless every precaution be taken. Freudenberg has related the history of two patients whose sera examined in a number of laboratories gave absolutely discordant results. Wassidlo made a systematic serodiagnosis in twenty cases and in 66 per cent. the results were contradictory. Many others have recorded similar diagnostic difficulties with the Wassermann. To explain these mistakes the antigen, the complement, the amboceptor, and above all the simplified rapid methods still resorted to by many laboratories under the name of the Wassermann test, have each in turn been more or less incriminated.

Then, as Golny of Geneva points out, besides the cases giving a distinctly positive or negative result, it must be recognized that there are other instances where doubt will exist, due either to previous treatment of the patient or to some peculiar state of his serum which is often but temporary and therefore requires a second or even a third essay, which, perhaps, will settle the question. This fact is so true that all the statistics published before 1910 gave insufficient results, with the exception of that due to Boas, which gave 100 per cent. of positive reactions in untreated cases presenting secondary accidents, while Fleischmann found only 96 per cent., MacDonagh found 97 per cent., and Blascheo, Citron, and Ledermann each found 98 per cent.

The statistics of the laboratory of syphilidography of the University of Geneva gave 98 per cent. up to 1911, but since this year, thanks to a very careful technique, Prof. Oltramare has had 100 per cent. positive results, and it is maintained here that a laboratory not obtaining these results must commit some technical error. Regardless of such mistakes, it must be admitted that the Wassermann reaction is an element of the highest order in the diagnosis of syphilis and the progressive extension made by this infection in the etiology of many morbid processes and dystrophies obliges the clinician to resort to it in a great number and variety of cases as it is frequently the only diagnostic means at our disposal in obscure pathological states.

It goes without saying that the case history and clinical signs retain all their value and the test treatment, so greatly in honor before the discovery of seroreaction, will still render appreciable service, but a positive Wassermann furnishes a confirmation which is far from being unimportant. It is, however, a method the exact clinical value of which must be known and appreciated in order order not to exact services from it which it is incapable of rendering.

The positive Wassermann is truly a cardinal symptom of syphilis, which may, however, be absent, just as the exanthema of scarlet fever may be wanting in some cases. When positive it greatly helps; its absence does not imply an absolute negation. It can be safely affirmed, according to the teachings of the Geneva school, that a positive Wassermann obtained in a chronic affection creates the obligation of regarding the case as having a syphilitic basis, and consequently a specific treatment is to be essayed.

Cases of psoriasis, lupus, or epithelioma which, after the discovery of a positive seroreaction, have been submitted to mercurial or arsenical treatment and have been cured or greatly benefited, often to the great astonishment of many, are now not uncommon. It is well known that psoriasis always gives a negative seroreaction, while on the contrary, psoriasiform syphilides give a positive Wassermann, and some are even of the opinion that this test is the best means we as yet have of differentiating between tuberculosis or cancer and syphilis.

In numerous instances of positive reaction, the syphilitic nature of a lesion of the aortic orifice will be made, the consequences of a specific aortitis the clinical diagnosis of which had previously been very doubtful. Besides such examples, we now know the immense service that this seroreaction can render in neurological and psychiatric practice, in the diagnosis of locomotor ataxia and general paresis.

The percentages of positive results obtained at the syphilidographic clinic of the University of Geneva, based on a total of 4500 Wassermann reactions, were:

During the primary lesion, 69; secondary syphilis with symptoms, untreated, 100; treated or not, 89; treated, 79; without symptoms, treated, 47. Tertiary syphilis in activity, 64. Tertiary syphilis without any evident lesions, 47.

UNIFORMITY NEEDED IN SHAPE AND SIZE OF PROFESSIONAL REPRINTS AND CIRCULARS.

To the Editor of the Medical Record:

Sir:—This is a plea for uniformity in size, shape, and arrangement in printed data which the physician may wish to preserve, conveniently file, and promptly refer to; such as: (*a*) Reprints of papers and (*b*) advertising data describing objects which deserve preservation and prompt reference.

The object of collectanea is convenience for filing and for reference. Heretofore I made recommendations that advertisers adopt a suitable system whereby descriptive matter, memoranda, etc., could be readily filed. One measure has been extensively adopted, viz., index filing cards of standard size, 3 x 5, also small, closely printed circulars or descriptive

booklets of the same size, 3 x 5, and containing several pages of outline. The fact is that many physicians now use index filing systems, kept in the drawer of a desk for short case notes, also another for other data. Inquiry and experience teach me that this custom of filing data is becoming nearly universal, and will become more so in proportion as the material is supplied in filable shape. Meanwhile all heterogeneous printed stuff in odd sizes and forms is thrown in the scrap, where it deserves to go.

Reprints of valuable medical articles suffer in much the same way. To collect and attempt to arrange them causes suffering, vexation, and loss of time to those who wish to preserve and later read them. Surely the editors or managers of medical journals should be at least as cooperative as some manufacturing concerns have now become. The subject is no trifling matter; is of fundamental significance.

J. Madison Taylor, M.D.

Philadelphia, Pa.

CLINICAL CURE OF MALARIA.

To the Editor of the Medical Record:

Sir:—All the remarkable cures are not reported through the medical societies or clinics. This is one I overheard in a Broadway car. The speaker was a man about sixty, earnestly giving information to his friend.

"Aw, the climate is different now. Why, years ago you'd get the agyer. It'd grab yer right on the sidewalk, and y'd shake for fifteen minutes, and nothin' u'd' stop it. I had it awful. I tuk everything that I heard of. And then I got the malaria. That's worse. It had me all the time. I went everywhere that anything was advertised, and to doctors who'd say they could cure malaria. But it was no use.

"Then a feller told me what to do. 'What you want ter do,' says he, 'is to git good and drunk. That'll knock the malaria out of yer.' So out I goes and starts it. I went up the line, takin' beer, gin and everything. And I kim down ag'in. And at Eighty-second Street corner I went into a place where was about forty steps goin' down to a cellar or basement. I tuk a big drink of whiskey there and started down the steps. What I wanted ter do, yer know, was to get them fightin' to knock out the malaria.

"I never knew nothin' till I woke up. I had nearly trun up me insides. Everything I had et for ten years musta come up. There was blood, too. A regular hemorrhage. It seems I tumbled down the steps. Well, I gets up and tuk two big drinks of French brandy and a chunk of ice as big as yer fist. That stopped the blood, and I've never had no malaria since."

For those who wish to try the remedy I would simply say that it is probably a trifle harder to follow the plan since January 16, and the exact location of those steps is not clearly indicated in the case as reported. But maybe any forty—count them—steps will do.

John G. Coyle, M.D.

220 East Thirty-first Street, New York.

7. Hemolytic Streptococci in the Normal Throat after Tonsillectomy.—H. B. Van Dyke, in view of the reports from civil and military observers during the last two years of the rôle of hemolytic streptococci, especially as secondary invaders in such diseases as influenza, lobar pneumonia, and measles, made a study of the incidence of these organisms in the throats of tonsillectomized individuals in good health. The series of fifty-five cases includes five females and fifty males, ranging in age from seven to thirty-three years. He found that in nine, or 16.4 per cent., there were markedly hemolytic streptococci. In sixteen, or 29 per cent., of the throats were the Brown's Alpha prime type. Thirty, or about 55 per cent., of the throats examined revealed no hemolytic streptococci. There seemed to be no significance in the time elapsing between the removal of the tonsils and the bacteriological examination of the throat for hemolytic streptococci. In several of the cases the Beta type of hemolytic streptococci was present in the absence of clinically visible changes in the throats. The fermentation reactions of these streptococci were typical of hemolytic streptococci. According to the classification of hemolytic streptococci by fermentation reactions as suggested by Holman, the organisms tested would be divided into two groups, *Streptococcus anginosus* (fermenting lactose, but not mannite and salicin) and *Streptococcus pyogenes* (fermenting lactose and salicin, but not mannite). The method employed by the writer differs from that of most investigators in that a routine preliminary cultivation of the throat cultures in blood broth was made.

8. The Abuse of Passive Movements. E. Stanley Brentnall.

5. The Schick Reaction for the Determination of Susceptibility to Diphtheria.—H. Mason Leete gives the results of an investigation made with a view primarily to the forming of some opinion as to the reliability of the Schick reaction, its difficulties, and its suitability for application in general and hospital practice, together with the advantages that might be expected to arise therefrom. The test is performed by injecting a very small dose of diphtheria toxin into the skin, and noting after a certain lapse of time whether there is a reaction produced or not. If there is a reaction the test is said to be positive, and this result indicates that the subject lacks natural antitoxin immunity, and is therefore more likely to be susceptible to diphtheria. This reaction is due to the irritating effect of the toxin on the skin cells. When the patient has circulating in his blood natural diphtheria antitoxin the injected toxin is neutralized, so that no local reaction is produced. The test is then said to be negative, and the subject

to be immune to diphtheria. The toxin injected is a ripened one which has been recently carefully standardized and its minimal lethal dose accurately determined. The minimal lethal dose is the smallest amount of toxin that will produce death in a 250-gram guinea pig within four days. Such a toxin is taken, and suitable dilutions made until the diluted toxin contains one-tenth of a minimal lethal dose in one cubic centimeter. The amount actually injected in the test is 0.2 c.c. of this diluted toxin, which therefore contains one-fiftieth of a minimal lethal dose. The tests were performed in the Edinburgh City Hospital, the majority upon patients newly admitted to the scarlet fever pavilions. In addition, tests were carried out in other wards for the purpose of detecting susceptibles and protecting them with prophylactic doses of antitoxin, the need having arisen. Some tests were performed on the medical and nursing staffs. In 57.2 per cent. of the scarlet fever patients the reaction was positive, and it was noted that the positive reactions diminished with increasing age. They were more frequent among scarlet fever patients than among normal adults. In a series of sixty normal adults only seventeen were positive, which gives a percentage of 28, as compared with 37.5 in the corresponding group of scarlet fever patients. One hundred and ten cases, all of whom had previously received therapeutic doses of antitoxin at periods varying from one to seventy days before the performance of the test, were tested, and all except one gave a negative result. Among the series of 500 cases tested eleven cases of mild diphtheria, confirmed by bacteriological examination, occurred. Of these ten had given a good positive Schick, and the other one had been classed as doubtful. Among a series of tests performed on members of the hospital staff, one subject who gave a negative result developed clinical diphtheria. This may be explained on the basis of the small margin of error that is always to be reckoned with. Among thirty-two carriers eighteen were negative and fourteen positive to the Schick test, showing that immunity may depend upon other factors than the presence of antitoxin. From this study the writer concludes that the Schick test appears to be of definite value in detecting diphtheria susceptibles, and as such has many possible applications. It is easy to perform and free from danger. A reliable toxin and careful technique are essential. Once the differences between a positive and a pseudo reaction are appreciated reading is easy, but if there is any doubt controls of heated toxin should be used. The best times for readings are twenty-four hours, three days, and ten days after the test.

8. **The Abuse of Passive Movements.**—E. Stanley Brentnall thinks it is time that the phrase "massage and passive movements," as loosely indicating a form of treatment upon which responsibility for future failure may be thrown, should disappear forever. While of value in a few cases, not only is it useless as a routine therapeutic measure, but in many cases it does definite and positive harm. It is for these reasons that machinery of the Zander type has been excluded from up-to-date physiotherapeutic departments. Voluntary movement, on the other hand, whether reinforced externally or not, undertaken at the right moment, is a valuable method of treatment, physiologically correct, carrying with it its own guarantee of safety. Considerations such as these emphasize the necessity of a single control——that of the surgeon—over the treatment of a patient, no matter whether in the outpatient department, the ward, the massage and electrical department, or the gymnasium. There is no doubt in the writer's mind that the system of "watertight" departments with separate heads is to be held to blame for a certain degree of permanent disability following injuries.

1. An Address on Clinical Research. Sir James Mackenzie.
2. Points in the Early Diagnosis of Pulmonary Tuberculosis. Thomas Beattie.
3. The Routine Treatment of Malaria in Uganda. J. A. Taylor.
4. A Comparison of Two Methods of Administering Arseno-benzol Compounds in Syphilis. H. E. Gibson.

1. An Address on Clinical Research.—Sir James Mackenzie, director of the recently organized St. Andrews Institute for Clinical Research, delivered this address at the opening of the Institute, his purpose being to give the reasons for such an enterprise. The many stumbling-blocks in the path of medical progress, he holds, are mainly due to the lack of understanding of the distinctive character of the science of medicine. The knowledge of disease is so incomplete that it is not yet known what steps should be taken to advance knowledge. It has been assumed that the methods which are suitable for various branches of science—as chemistry and physics—should be applied to medical investigation, but the methods of these sciences are not applicable to the investigation of the most important phenomena of disease. The methods which have helped some sections of medicine—as physiology and bacteriology—are not applicable by themselves to the wider fields of clinical medicine. The present-day conception takes too narrow a view of the field with which medical science has to deal. It assumes that instrumental methods are of necessity the only scientific methods. It has been assumed that because recording and measuring instruments and other methods have greatly advanced such limited fields of medicine as physiology, bacteriology and chemistry, therefore clinical medicine should adopt the same method. In medicine there are phenomena which the scientific instruments of to-day, however delicate, can neither register nor measure, and there are methods necessary for the investigation of disease which no laboratory experience can supply. As an outcome of this misunderstanding, large fields for investigation which are essential to the progress of medicine have been ignored, methods and principles have been unrecognized or imperfectly applied, while the appropriate investigator has been neither trained nor encouraged to do the work which he alone has the opportunity to perform. The present scheme, the writer declares, is not antagonistc to the investigation in other fields of research, nor is it the intention to substitute this scheme for others. The contention is that there are fields essential to the progress of medicine which have been neglected, and to some of these fields it is the intention of the Institute to devote itself, using the methods which are suitable for the purpose. The aim is the prevention of disease, and therefore the relief of suffering. The problem being the prevention of disease, a complete knowledge of disease in all its aspects is necessary before steps can be taken to prevent its occurrence. The first principle laid down is that as disease is made manifest only by the symptoms it produces, it is imperative that the first step should be to understand the nature and significance of symptoms. Developing the subject from this point, the writer discusses the early stage of disease; the nature of the predisposing conditions; the neglect of symptoms; the test of experience; the choice of the general practitioner as investigator; the training of the observer; the principles of investigation; differentiation; classification; the law of progression; the law of associated phenomena; the significance of symptoms (prognosis); the use of laboratory methods; the class of patients. Regarding the expectation of results, Sir James warns against any immediate achievement of the chief aim in medicine, the prevention and cure of disease. A long and weary road must be traveled. Being trained in the detection of symptoms, the immediate object is to find out the nature of the symptoms of disease, by discovering their mechanism, and by watching individuals to see what happens. In this way the onset of some diseases may be detected. After that it will be necessary to search for those who show the early signs of a particular disease, and recognizing these signs, seek then for the cause and the factors that favor its onset. If the contemplation of such work seems discouraging, it must be borne in mind that all great enterprises are based on work that has been done by individuals whose part is lost in oblivion.

4. **A Comparison of Two Methods of Administering Arseno-Benzol Compounds in Syphilis.**—H. E. Gibson made a comparative study of the administration of arseno-benzol compounds by the "concentrated course" and the "prolonged course" methods. In the first series of cases treatment consisted of one dose of 0.3 gram of kharsivan, followed at weekly intervals by doses of 0.6 gram, until a total of 2.7 grams had been

given, but an interval of fourteen days was allowed between the third and fourth doses. This course was thus completed in five or six weeks. In the second series of cases, three injections of 0.3 gram were given, then two of 0.4 gram, and two of 0.5 gram, all at weekly intervals, except for a fortnight's rest between the third and fourth injections, as in the other series. This course lasted about eight weeks, and the drug was given intravenously, as in the "concentrated course." Further treatment, if necessary, consisted, as a rule, of intramuscular injections of novarsenobillon, at weekly intervals, generally one of 0.3 gram and one of 0.6 gram. The criterion of cure was a negative Wassermann reaction. From this study the writer concludes that advantages seem to lie with the prolonged course, partly owing to the lesser incidence and violence of reactions, and partly because the total results are better than with the concentrated course, especially in secondary cases. Should a patient showing only a primary sore have urgent reasons for wanting a short course, the concentrated course may be given, but otherwise it is better to spread the treatment out over a longer period.

Sensibilization of Mucous Membranes of the Guinea Pig to Gonococcus Infection.—Besse and Christides of Professor Buettner's Geneva Clinic report numerous experiments on the guinea pig in reference to the laboratory diagnosis of gonorrhea. In the work of others it does not appear that this line of investigation was promising, but apparently the experiments were limited to inoculation of the conjunctiva. The authors made use additionally of inoculation of the vagina with subsequent study of the uterus and tubes and have satisfied themselves that the guinea pig is the only animal which can be made to take gonorrhea. To make the animals more susceptible they were given a diet rich in sugar, while at the same time their ordinary food was reduced to a minimum. However, it was thought best to guard against emaciation. Gonorrhea pus was smeared on the cervix uteri and conjunctiva and both a cervicitis and conjunctivitis was produced. The experiments were varied in various ways, as by the use of pure cultures instead of smears of pus, by introduction beyond the cervix and into the rectum, etc. Two out of three pigs died of general gonococcic infection. The authors concluded that despite the interesting results the method could not be used in laboratory diagnosis. The work on the predisposing influence of diet will be continuued and beer and malt tested for this purposes, since beer will arouse the latent disease in man.

What Are Vitamines?—Tschirsch carries this subject back to the labors of Eijkman in 1897 and Stepp in 1909. We have knowledge of two groups of these bodies of which one is soluble in fats and insoluble in water and alcohol, while the other is soluble in water and alcohol but not in fats, ether, or acetone. It is certain that the animal body cannot form vitamines and that they reach the body through vegetable foods. We know little about them save that they can act in minute quantities and are fairly resistant, requiring a heat of 120° C. to destroy them. It seems evident that they are close to the enzymes. The animal is notably a much poorer chemist than the plant, and even the algæ are better chemists than the body of man; for they can utilize the nitrogen and carbon dioxide of the air. Study of plant chemistry shows that something in the vegetable kingdom can close the ring in hexacyclic compounds. The author gives many examples, as when acyclic lysin is transformed to cyclic piperidin and pyridin and acyclic hexose into cyclic inosite and pyrogallol, gallic and benzoic acids, etc. We may therefore assume that vitamines are necessary in the animal organism to close up certain half-closed ring combinations. The author terms them cyclocliases and assumes temporarily that they are enzymic, although he does not regard them as mere catalysts. The reactions which they make possible need not be limited to ring closure.

Complemental Factors of Growth and Equilibrium.—Thiébaut begins his article with an allusion to vitamines. It has been shown that these mysterious substances occur in the vegetable as well as animal kingdom. Here, however, they are known as auximones to prevent confusion. The two substances are known as secondary factors of growth and equilibrium. Primary factors are of course protein, fat, carbohydrate, etc., and the vitamines behave as complemental to these. The great question relates to the mechanism, for thus far we know a vitamine chiefly through deficiency symptoms. We may think of a catalytic or diastasic activity, using the two terms as for the time synonymous. The rapid extension of our knowledge of electrons in physics makes it possible to think of the action of vitamines in the same connection. But while we have been accustomed to state that enzymes act by catalysis the author points out essential differences. Thus a diastase acts in a colloid medium and the quickness of action varies with the viscosity of the medium. It has recently been shown that every isomere of an organic combination has a specific diastasis, and this law brings the subject nearer the domain of electronics. In other words, the molecular grouping in stereochemic isomeres can only be motivated by electronic grouping on a colloidal surface. Aside from this specific behavior of isomeres, diastasic and catalytic actions are of the same type.

A New Phenomenon of the Pyramidal Tract.—Barré sums up a clinical study of a new leg maneuver practicable in paralyses and pareses as follows: The question posed is the effect of voluntary impulses on the muscles of the lower extremities. When fairly elicited the sign means that voluntary motricity is paralyzed and is of value in discriminating between functional and organic states and in excluding organic spastic hemiplegia, etc. The patient lies prone, with the legs flexed at right angles to the thighs. He is told to hold the pose and then at a word to relax. The normal man will hold his leg vertical for a long time without effort, but if there is any impairment of the pyramidal path the leg will begin to lower itself, the phenomenon varying with the severity of the case. In total paralysis the leg drops instantly and in minor degrees may slowly sag down or fall in a cog wheel manner of intermission. Upon this basis an entire series of induced phenomena may be isolated in nervous affections..

November, 1919, viii, 11.

Value of Different Incisions for Laparotomy.—Rouffart at the close of a long article on this subject concludes that the median longitudinal incision while responding to every exigency of the operative act, gives occasion at times to eventration, which is especially frequent in healing by second intention. Every longitudinal median incision should therefore be sutured by a method which permits the reinforcement of the cicatrix by the muscular tissue of the recti. Every longitudinal extra-median incision which divides the muscles and disturbs their nutrition by section of the nerves should be rejected as predisposing to eventration. The superiority from the anatomical and clinical viewpoints of the transverse incision over the longitudinal incision should make it preferable in the majority of obstetrical and gynecological laparotomies.

Radium Therapy of Cancer of the Uterus.—Degrais in his brief article considers primary epithelioma of the cervix and postoperative recurrences. The former he divides into operable and inoperable. In the former the surgeon believes that his cases which escape operative death and ordinary recurrence will survive from 6 to 8 years and radium can hardly better such a result. It is true that we have but few cases to serve as a basis of study—cases in which the knife has been point blank refused. The author has cases of primary

epithelioma in which radium alone was used which are living 5 or 6 years after the application of radium, and one case in which survival is now 8 years. This was a papillary growth in which not even a preliminary curettage was used. As a rule the author makes use of the curette under the circumstances. The results in the author's series of cases have been typical throughout, the appearance of the cervix depending on the amount of tissue originally involved. Thus in certain cases the cervix was almost as if amputated. In the use of radium in recurrence the author does not speak of cure but has invariably secured benefit and prolonged life, often over long periods. The curette is always used as accessory. In the third type of case, the postoperative recurrence, radium has its peculiar usefulness. He cites one case of precocious recurrence in which radium stepped in and gave the patient at least 6 years more of life.

Injection of Adrenalin in the Diagnosis of Latent Diseases.—Dazzi refers to the value of this and similar resources in obscure affections, with especial reference to chronic malaria. The basic disease-process may of course be masked by some other more accidental condition. The practitioner may feel quite certain that a given subject has latent malaria but if he finds no parasites in the blood he is nonplussed for the moment. There may be present oligemia, enlarged spleen, fever having no special type and urobilinuria. The blood count and the pigmented leucocytes may strengthen the supposition. It is true that we have provocative tests of some value such as cold baths and various serum inoculations while adrenaline has been used as a hypertensive for this purpose as have also pituitrin and ergot. Numerous other attempts have been made with a view of mobilizing the hematozoon in the spleen and driving it into the blood, there to set up a malarial chill and fever. The spleen has been faradized and the various fever producing substances injected. The author has injected sterile milk, strychnia, iron, iodides, salvarsan, ergotine and adrenaline in the search for a provocative and finds that 1 mgm. of adrenalin is most dependable. He reports twenty cases in which he used the resource. He was guided by the appearance of the parasites in the blood rather than by clinical manifestations. The temperature rise seems to have been very slight but the spleen became reduced in size as a result of the injection while parasites appeared, at first one or two to a field and later 6, 8, or more. In but one case did the injection cause a typical malarial paroxysm.

Norsk Magazin for Laegevidenskaben.

December, 1919, lxxx, 12.

Cancer of the Rectum.—Bull reports a series of forty-four operative cases of this affection which include seven forms of intervention. The favorite was the Kraske with fourteen cases and three operative deaths and next came the dorsococcygeal or Kocher operation without mortality. The third in frequency was the combined method, six cases with one death. There were five perineal interventions without removal of the coccyx and four others in which the bone was removed —no operative deaths in these perineal cases. There were four cases of anal intervention with one death and one abdominal case without mortality. Total five operative deaths. In regard to remote results there were twelve clean cut recoveries while seven others survive but have not passed the three year mark. Eighteen patients are dead of recurrence and two others have died from causes not connected with the cancer or its treatment.

Influenza Pneumonia.—Hatlehol reports a large material of cases from Professor Laache's clinic at the Rikshospital, Cristiania. Instructive is the comparison with the pandemic of 1890. Warfvinge at that period recorded 325 cases of pneumonia from Swedish sources with a mortality of 25.5 per cent. During the recent pandemic figures from four leading Scandinavian clinics give 814 cases with 296 deaths, a mortality of 36.4 per cent. In the author's clinic the total number of cases treated was ninety-four and of these twenty-seven ended fatally. The third decade of life gave the highest incidence as well as the highest mortality save that naturally the percentage death rate was higher in the elderly. The third decade was the deadliest of the first four decades. Of the author's ninety-seven cases eleven were pneumonias from the start while the balance were secondary or complicating cases. It is of interest to learn that in 1803 one Nelson described a form of influenza accompanied by hemoptysis. Nearly half the author's cases showed hemorrhagic sputum although this term comprises everything from reddish expectoration to pure blood. The percentage of empyemas was eleven.

Dangers of Infection from Various Common Articles Contaminated by Tubercle Bacilli.—Lawrason Brown, S. A. Petroff, and Gilberto Pesquera of the Trudeau Sanatorium report the results of inoculation into guinea pigs of various substances and washings of objects that are ordinarily presumed to be contaminated with tubercle bacilli. Dust collected by a vacuum cleaner from the rug of a living room in the sanatorium was negative; swabbings from the mouthpiece of the sanatorium public telephone were negative. Washings of spoons, forks, glasses, and cups, that had been used at meals by patients and had not been cleansed were positive; those of knives and dishes were negative. Washings of the hands of patients who had coughed upon their hands were positive; those of the hand of a second person who had shaken hands with a tuberculous patient, and those of a door knob rubbed by a contaminated hand were negative. Saliva collected from patients just before coughing was positive. Patients with positive sputum kissed Petri dishes: washings of the dishes kissed, immediately and ten minutes after coughing, were positive; those, twenty minutes after cough, negative. The wash water of a tooth brush was positive; as were the fly specks of flies fed on tuberculous sputum.—*American Review of Tuberculosis*, December, 1919, Vol. III, No. 10.

Death Following Novocaine Administration.—Schoemaker reports the case of a man of 42 whose stomach disorders were clearly shown to be due to an epigastric hernia. His health was otherwise perfect. It was decided to operate and first a hypodermic of morphine was given. An hour later he was placed on the table and the usual injection begun of novocaine and adrenalin. At the first needle prick he turned pale, the pulse becoming small and weak but he was given the injection. The assistant who had figured in many local anesthesias encouraged the man a little and continued to infiltrate the skin. The patient now seemed quite normal, but before the completion of the infusion (8 punctures had been made) he rose up and fell from the table. He was then cyanotic with spasmodic respiration, pulse very small and weak. He was at once given a hypodermic of camphorated oil and ether and his heart was massaged but death took place in a few minutes. Autopsy revealed persistent foramen ovale, diameter 1.5 cm. No or only slight status thymicolymphaticus. The only other find aside from the hernia was lobular kidneys. The first shock which occurred at the moment of the needle prick was psychical, as nothing had as yet been injected. The patient had quite rallied when the real collapse came. The quantity of novocaine injected was small and in 6,000 injections the author saw but few examples of collapse and no serious results. A reflex inhibition of the heart and an injection into a venule seem out of the question. —*Nederlandsch Tijdschrift voor Geneeskunde.*

Cancerous Degeneration of Fibroids Following Radiotherapy.—Delbet has seen some particularly malignant cancerous transformation of fibroids in cases which had been submitted to radiotherapy. It is, of course, impossible to show that the condition did not preexist, but the author thinks it adds greatly to the responsibility of treating fibroids by this means. A debate on the subject took place in the Société de Chirurgie. The question is does the treatment aggravate the course of the cancer. It was also agitated whether the results attributable to radiotherapy were sufficiently favorable to justify the risk. No consensus of opinion was reached.—*Gazette des Hopitaux.*

Book Reviews.

VICIOUS CIRCLES IN DISEASE By JAMIESON B. HURRY, M.A., M.D. (Cantab.) Third Edition. Philadelphia: P. Blakiston's Son & Co., 1919.

THE third edition of this work appears six years after the second and is considerably larger than that edition. Some of the enlargement is due to rewriting or revision of the matter found in the previous editions, but much of it is added material presenting vicious circles as they are found in veterinary and plant diseases. It is of course well known that vicious circles appear in a great many of the pathological conditions which present themselves before the physician, but the average practitioner is prone to regard them merely as a logical and expected portion of the disease complex. In this work vicious circles are detected in numerous conditions and are picked out and collected in one volume. The text is reinforced with numerous quotations from authors who have used the term vicious circle and one feels that some one must have told the author there was no such thing and as a result he has written this book to prove its existence. It is moderately interesting, but since the vicious circle is not in itself an entity, can have but slight practical value.

THE NARCOTIC PROBLEM. By ERNEST S. BISHOP, M.D., F.A.C.P., Clinical Professor of Medicine, New York Polyclinic Medical School; Member Narcotic Committee, Conference of Judges and Justices of New York State; Committee on Habit Forming Drugs, Section on Food and Drugs, American Public Health Association, etc. New York: The Macmillan Company, 1920.

IN this book of less than two hundred pages, the author presents two vital elements which have received insufficient consideration,—first, the sufferings and struggles and problems of the narcotic addict, the other, the nature of the physical disease with which he is afflicted,—discussing and correlating various elements and conflicting activities in an effort to help each one actively concerned to appreciate the relation of his own endeavor to the whole narcotic drug problem. With this in view he gives attention to fundamental considerations; the nature of narcotic drug addiction-disease; the mechanism of narcotic drug addiction-disease; methods of treating narcotic drug addiction; the rational handling of narcotic drug addiction-disease; relation of narcotic drug addiction to surgical cases and intercurrent diseases; laws, and their relations to narcotic drugs; comments upon the legitimate use of narcotics in peace and war; and a general survey of the situation and the need of the hour. In an appendix he gives "human documents,"—statements of sufferers from narcotic drug addiction-disease. The hope of the future lies in the change of attitude from "What shall be done *with* or what shall be done *to* the narcotic drug addict to make him stop using drugs?" to "What can be done *for* the narcotic addict to relieve him of the physical necessity of using drugs?" and "What can be done to so educate the public as to the facts of addiction, that this disease will claim as few victims as possible?" While some narcotic addicts are inherently irresponsible, vicious or defective, demanding care and restraint irrespective of their addiction, the mass of addicts are clinical problems of internal medicine, victims of a definite disease, characteristic in its symptomatology, reactions and phenomena, a disease which will before long, in the author's belief, come to be known as clinically and therapeutically controllable and arrestable.

THE PROCEEDINGS OF THE CHARAKA CLUB. VOL. V. New York: Paul Hoeber, 1919.

IT is three years since Volume IV of these proceedings appeared. This one is rather smaller than the former number but not less interesting, and it is gratifying to note that the size of the edition is larger than previously. Several of the articles have to do with military surgery of olden times and there are many excellent illustrations of ancient surgical instruments. There is a brief play by Dr. Bailey, a description of the oldest known Latin version of Aristophanes by Dr. Gerster, and a critical discussion of Chesterton's new play, "Magic," by Dr. Jelliffe, among the contributions. This sort of publication is interesting in many different ways and it is very pleasing to know that the interest in historical medicine is being maintained by such a representative and able set of writers as are found among the members of the Charaka Club.

THE ERRORS OF ACCOMMODATION AND REFRACTION OF THE EYE AND THEIR TREATMENT. A Handbook for Students. By ERNEST CLARKE, M.D., F.R.C.S., Ophthalmic Surgeon to the King George Hospital, Queen Alexandria Hospital for Officers; Consulting Surgeon to the Central London Ophthalmic Hospital; Consulting Ophthalmic Surgeon to the Miller General Hospital. Fourth Edition. New York: William Wood & Company.

THE present edition of this practical handbook, the first edition of which appeared fifteen years ago, presents the same subject matter carefully revised and brought up to date, some chapters being rewritten. The author has held to the idea of omitting all data which are unnecessary for the busy practitioner or the overburdened student.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. December 1, 1919. Philadelphia and New York: Lea and Febiger, 1919.

THE current number of Progressive Medicine contains chapters on Diseases of the digestive tract and allied organs, the liver, pancreas and peritoneum, by E. H. Goodman; Diseases of the kidneys, by H. A. Christian; Surgery of the extremities, shock, anesthesia, infections, fractures and dislocations and tumors, by W. E. LEE; and practical therapeutic referendum, by H. R. M. LANDIS. The whole number is of interest, and the section on Surgery goes far to clarify the discussion on the value of many procedures evolved during the late war. The paragraphs on alcohol have a timely value, particularly the remarks on wood alcohol and the summary of the rights of physicians and druggists in the matter of prescriptions calling for alcohol.

OUTLINES OF ORGANOTHERAPY. By HENRY R. HARROWER, M.D., late Professor of Clinical Diagnosis, Loyola University, Chicago; Fellow of the Royal Society of Medicine; Member of the Association for the Study of the Internal Secretions, etc. 1918: Published by the Author, Glendale, California.

THE literature of Organotherapy is enormous; and the author of these "Outlines" has added this little volume to the mass for the special benefit of "the busy physician who has no time for reading." The book begins with an interesting chapter dealing with the general principles of the subject. The author then goes on to discuss briefly some forty organotherapeutic remedies. He divides these remedies into three classes: (1) The better known organotherpeutic remedies; (2) less well known but useful products; and (3) extracts used infrequently. In the first class there are only ten entries, and the beginner in this method of therapy will find this the most interesting section. The author gives information on the source and form of the remedy under discussion, its physiologic relations and action, principal therapeutic indications, contraindications, synergists, administration, and dosage. The book should prove useful to "the busy physician who has no time for reading."

THE REFRACTION OF THE EYE. A Manual for Students. By GUSTAVUS HARTRIDGE, F.R.C.S., Consulting Surgeon to the Royal Westminster Ophthalmic Hospital; Ophthalmic Surgeon and Lecturer on Ophthalmic Surgery to the Westminster Hospital. With one hundred illustrations. Sixteenth Edition. Philadelphia: P. Blakiston's Son & Co., 1919.

THIS edition of the familiar manual, the first edition of which appeared in 1884, maintains the original plan, with careful revision and various additions. The old measurements have been purposely omitted in favor of the metric system.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, Held January 15, 1920.

FIRST VICE-PRESIDENT, DR. JOHN A. HARTWELL, IN THE CHAIR.

Report of the President.—Dr. GEORGE DAVID STEWART submitted this report which showed that the activities of the New York Academy of Medicine during the year 1919 had increased; men in the service had returned; fifty-seven new members had been added, and there was a large waiting list of candidates. A new building badly needed for housing the activities of the Academy, and for which plans had already been drawn, had been held back by the increased cost of material and labor. Consultations with their architects and with their Financial Advisory Committee, and such information as was obtainable from other sources, made it appear extremely probable that the cost of building and labor would not be materially lessened in the next few years. It was proposed therefore to begin the erection of this building as soon as possible on the plot next to the Academy. By the will of the late Dr. Jacobi a legacy of $5,000, to be added to the Philippine Meyer and Ernest Jacobi Library Fund, was bequeathed to the Academy, and in addition his valuable library of medical and medico-historical books, journals, and drawings. Thus Dr. Jacobi's devoted friendship for the Academy did not cease with his life, but went on and on. When the unexpended balance of the Physicians' Families War Relief Fund was recently distributed to its original donors, certain of these persons generously gave their share of the fund, amounting to $21,735 to the Academy to be added to the Academy Extension Fund. Among these contributions was one of $10,350, representing the amount that had been donated by the late Dr. E. B. Cragin to this war relief fund. The treasurer's report, while it showed a comfortable and gratifying balance did not permit any relaxation of their efforts to secure additional funds for the Academy—funds which would be absolutely necessary if the Academy was to maintain its rank as an educational factor in the science of medicine.

Report of the Council.—Dr. WILLIAM A. STOWELL submitted this report, which showed that the Committee on By-laws had completed the task of revision of the by-laws so that a new book might now be printed. The Public Health Committee had this year given special study to the control of venereal diseases and to the dispensary conditions in this city. Their advice was frequently sought on public health matters and plans. Realizing the need of greater housing facilities, the president had appointed a building committee consisting of Drs. John A. Hartwell, Seth I. Milliken, Reginald H. Sayre, Walter B. James, Lewis F. Frissell, Charles H. Peck, Charles L. Dana, Nathaniel R. Norton, and the President of the Academy ex-officio. The scientific sections all reported good work during the year, the greatest popularity being that of Orthopedic Surgery and Ophthalmology, the former having an average attendance of ninety-six and the latter eighty-eight.

Report of the Committee on Library.—Dr. LEWIS F. FRISSELL and Dr. WARREN COLEMAN submitted this report, which showed that the attendance of readers during the year 1919 was 23,500, 6,000 greater than during the preceding year, and within 1,000 of as great a number as in the year 1917. This had again brought before the committee the problem of the overcrowding of the Library and the lack of adequate reading room space. Fewer volumes, 2,468, had been acquired during the past year than in any previous year of the last decade, for several reasons. First, because the number of medical publications had been greatly diminished by the war, and because, in view of the shortage of stack room, the committee had exercised more than usual scrutiny of books published, excluding many volumes bearing on allied subjects but not strictly medical. The number of pamphlets added, however, had been greater. This report included suggestions for increasing the stack room.

These reports, together with the reports of the Board of Trustees and the Treasurer, were adopted.

Dr. RUDOLPH MATAS was elected an honorary member of the Academy.

Bad Results Following Operations for Chronic Appendicitis.—Dr. CHARLES L. GIBSON presented this paper, which was based on a study of 355 cases in the New York Hospital from July 1, 1913, to July 1, 1919, in which the appendix was removed. He said that as his paper was largely statistical he would not read it in full but would permit the tables to tell the story. This study involved two questions; first, why did they find that the removal of a supposedly diseased appendix failed so frequently to relieve symptoms, and, second, what was the reason of these failures and how could they be avoided? The removal of the appendix for clinical appendicitis had been accompanied by good results. There was, however, a class of patients with somewhat indefinite symptoms, the vagatonics, who were frequently subjected to operation needlessly and recklessly. After mentioning the conditions that might be mistaken for appendicitis, Dr. Gibson cited statistics showing that their bad results had fallen from 28 per cent. in 1913 to 11 per cent. during the last six months of 1919 in proportion as they had abandoned the small inguinal incision for a larger incision. It was of interest that appendicitis occurred more frequently in males than in females, about two-thirds of the cases being males. There were fortunately fewer conditions to obscure the diagnosis in men than in women. Another point of interest was that the larger proportion of the cases was among English-speaking people. The chief symptoms in their order of frequency were pain in the right lower quadrant, pain and vomiting, pain in the epigastrium, pain and constipation. In summarizing, Dr. Gibson stated that a large incision allowed of a more complete examination, and this was important inasmuch as one of the reasons for many of the bad results following appendectomy was a failure to look for and recognize other conditions coincident with the appendicitis. The improvement in their statistics was in a large measure attributable to more thorough work in looking for complications, especially in women. In order to avoid disappointing results following appendectomy for chronic appendicitis a comprehensive total history and a thorough physical examination were essential. One should exercise more caution in searching for complications in women than in men. Operations on neurasthenics should be avoided. There was no advantage or success attending the removal of the appendix alone when the symptoms of upper abdominal disease were present. The point especially to be stressed was that one should not cease to look for complicating conditions and in the search for these should make a supplementary incision if necessary.

Dr. CHARLES H. PECK said he agreed with Dr. Gibson in most of the points he had brought out and felt that he had covered the subject so thoroughly that there was little to add. During the five years from 1910 to 1915, one thousand seven hundred and forty-eight appendectomies were performed at the Roosevelt Hospital, nine hundred and sixty-five for acute and seven hundred and eighty-three for chronic appendicitis. The statistics for the five years from 1915 to 1920 had not yet been gone over, but assuming a similar number, it means that about three thousand five hundred appendiectomies had been performed during the past ten years. Approximately about two-fifths of these were classed as chronic appendicitis; of these, two main classes could be considered, first, those that had had definite acute or subacute attacks and came for an operation in the interval. Unsatisfactory late results are rarely seen in this group. The second group were those which had never had definite attacks, but which presented chronic symptoms of various types. It was in this group that most of the disappointing results following operations occurred. The first and most important cause of failure to cure faulty diagnosis, due to either an incomplete and hasty study of the case, or to errors in interpretation of the findings. Second, failure to make a proper exploration at the time of operation. It had been their custom, in practically all cases of operation for chronic appendicitis in the second group, to make a right rectus incision, through which careful exploration was made, including examination of the stomach, duodenum, gall bladder, biliary ducts, and pancreas, the line of the colon, the region of the

right kidney and ureter, and, in women, the pelvic organs. The exploration was rapidly made as a rule, before the appendix was even looked at. Duodenal and gastric ulcer, disease of the biliary tract, right ureteral calculus, omental and peritoneal adhesions (Jackson's membrane, Lane's kink), involving especially the ascending colon and ileocecal region, and disease of the pelvic organs in women, were the lesions most often confused with chronic appendicitis. If these were excluded or confirmed by systematic routine exploration at the time of operation, assuming of course, that every possible effort to do the same had been made by a careful preoperative study of the case, the liability of disappointing post-operative results would be greatly reduced. The third cause of failure might be the formation of postoperative, omental, or peritoneal adhesions. It was the speaker's belief, strengthened by observations made in many secondary laparotomies, that many cases of postoperative peritoneal adhesions were due to the carrying in of iodine on hands during operation. With the protection of the skin and wound edges by towels this was theoretically guarded against, but slips in technique easily occurred and he believed that this is a real danger which should be borne in mind. Finally, in determining indications for removal of the appendix, a correct conception of the pathology of appendicitis should be borne in mind. To understand this, the appendix should be examined *in situ* before its removal. The real lesion was practically always an obstruction of the lumen, incomplete in quiet stages. When it became complete for any reason the increased intra-appendicular tension soon produced circulatory and secondary infectious changes, *i.e.* acute appendicitis supervened. This partial obstruction was due to many causes, among which the most important were a short mesenteriolum, causing angulation at the base; peritoneal bands, old inflammatory adhesions, and in a quite important group of cases, a drag upon the mesenteriolum by an overloaded, mobile cecum. Many of these appendices, as truly pathological as an acutely inflamed one, showed relatively nothing abnormal when stripped from their surroundings and removed. The removal of such an appendix was always justifiable and a benefit to the patient, whatever associated lesions might have been present and overlooked or ignored. To summarize then:—One should guard against failures and disappointments by careful preoperative study and diagnosis. Second, by thorough exploration at time of operation. Third, by careful technique, avoiding undue trauma or chemical irritation of the peritoneum, which might result in postoperative adhesions.

Dr. Robert T. Morris said Dr. Gibson was right in his contention that the chief reason for unsatisfactory results after appendectomy was incomplete diagnosis. It seemed to him we were in need of a better definition of what was meant by chronic appendicitis. Did we mean fibroid degeneration and lymphoid hyperplasia of the kind one found in vagotonic patients? In patients belonging to the vagotonic class treatment with belladonna was sometimes better than operation. Many unnecessary operations were done upon these patients. Did we mean an irritative lesion, not due to infection, as it appeared in a fibroid degeneration or on the other hand an appendix that had become involved to a greater or less degree in scar tissue following an acute infective invasion. Complicating an infective invasion one might have a gastric ulcer and involvement of the gall bladder or pylorus due to the selective affinity of certain tissues for bacteria or toxins as Rosenow had shown. In the latter condition if other complicating abdominal conditions were present, a large incision might be needed for appendix operations, but if diagnosis was good enough and selection of cases good enough a short incision would often suffice. In the way of diagnosis there were two chief signs upon which one might place dependence. When a chronic irritative appendicitis had registered its nerve impulses on certain sympathetic ganglia for a fairly long time the muscular coat of the ascending colon became wearied and as a result it became lax and distended with gas and this gave what he had termed the "cider barrel" sign, that was, percussion on the left side of the abdomen elicited a sound like that of the cider barrel in October, while percussion on the right side gave the sound of the cider barrel in March. The second sign was hypersensitiveness at the site of the second and third sympathetic lumbar ganglia on the right side. This might be elicited by pressing on the abdomen one and one-half inches to the right of the umbilicus and a trifle below. As to the effect of iodine on the peritoneum, his experience with dogs and other animals in which iodine had gotten on the peritoneum was that subsequently adhesions were found regularly. He now made sure that iodine was washed off with alcohol before making the skin incision. In rabbits one nearly always got some adhesions no matter how careful he might be in abdominal work, and even though he used Ringer's solution or isotonic saline. Finally if one needed a long incision, he should make it; if a long incision was not necessary the surgeon should allow the patient to escape from a serious attack of surgery by employing a short incision. If he had developed skill in diagnosis he should allow the patient the advantage of any such acquired skill.

Dr. L. T. LeWald said Dr. Gibson had spoken of the need of studying patients by means of the *x*-ray. He thought the time was not far distant when all would agree that no case of supposedly chronic appendicitis should be operated upon until after a careful *x*-ray study had been made. Roughly speaking, in a series of cases of ptosis, the appendix had been removed in nearly 50 per cent. of them. In other conditions, such as a case that was mentioned in which five or six months after the removal of the appendix, a diagnosis was made of a tuberculous cecum, which might have been detected prior to the operation if a careful *x*-ray study had been made. Among conditions which might lead to a mistaken diagnosis of appendicitis and upon which the *x*-ray would throw light were cecum mobile, ulcer of the stomach, gallstones, renal calculi, subacute and chronic right-sided pleurisy, peculiar cases of partial dilatation of the colon, megacolon or elongated sigmoid. Occasional attacks of partial volvulus might give symptoms simulating appendicitis. In addition to the detection of other conditions which might account for the symptoms of appendicitis, with the *x*-ray one might sometimes absolutely *confirm* the diagnosis of chronic appendicitis. Sometimes definite concretions were discovered in the appendix by means of the *x*-ray, some of the bismuth getting into the appendix and coating the concretions so that they became opaque.

Dr. W. Gill Wylie said he felt compelled to take part in the discussion because he was one of the first surgeons to perform an appendectomy when he was connected with Bellevue Hospital and abdominal surgery was unknown. He expressed the opinion that the majority of these cases of chronic appendix began early in life, and he explained how, as man had evolved from the lower animals, the appendix had degenerated. The appendix had a check valve which allowed a secretion which the appendix produced to pass through. It was this arrangement which had degenerated. Another difficulty was that the products of digestion were held at a point where the small intestine joined the head of the cecum. A great many children who were poorly developed, weak, or not properly fed had trouble when the food, especially cow's milk, reached the cecum. An accumulation of fecal matter resulted, the appendix got out of order and the check valve was stretched. From the symptoms he could be so certain when this condition was present that he had frequently prophesied that an open appendix would be found and he was usually correct. He had found that when a child of this kind over-ate on the following day it would have an attack of pain, vomiting, and nausea with a slight rise in temperature. If one then gave castor oil the symptoms were relieved. By exercising care in the diet such a child would go along for weeks or months without an attack, but if there was an indiscretion in diet, there would be another attack. By giving a Seidlitz powder and producing a good movement and so getting rid of gas, one could feel the distended appendix and could touch the tender spot. Dr. Wylie emphasized the point that he always made it a practice to put the patient in good condition before operating even if it took three weeks or three months to do this, and he called in a specialist if such special help was needed in order to put the patient in good condition for operation. By properly treating these attacks of pain,

nausea, and vomiting as he had described one did not have so many cases of chronic appendicitis. In operating within the abdomen, Dr. Wylie said he never used anything like iodine unless he immediately washed it off with alcohol, because iodine penetrated through the tissues and gave rise to adhesions. Another point was that he never used pressure in any abdominal operation for pressure encouraged hemorrhage. If one did not leave the abdominal walls free the tissues inside the abdomen would be injured with resultant fixations, adhesions, and pain.

Dr. GIBSON, in closing, said that as regarded the *x*-ray they were not entirely ignorant of its preoperative use. A number of *x*-ray examinations had been made in each class of cases and, paradoxical as it might seem, the cases studied longest gave the worst results. While Dr. Peck was speaking of adhesions it occurred to him that this paper might be useless since during the last six months their results had been considerably improved and that it might be due to a forgotten point, namely, that in December, 1918, they began the use of picric acid, a five per cent. solution in alcohol, and they had been using it ever since. One of his staff was now studying the effect of picric acid on the peritoneum. It might be that this would prove to be a distinct improvement; certainly they had had very remarkable results during the past six months.

SECTION ON SURGERY.

Stated Meeting, Held January 2, 1920.

DR. SEWARD ERDMANN IN THE CHAIR.

Exploratory Thoracotomy for Chronic Empyema.—Dr. ALLEN O. WHIPPLE presented three patients, illustrating a type of procedure that had advantages in certain cases of chronic empyema which had previously been operated upon or in which the pus collection was of long standing with marked collapse of the lung. After relating in detail the history of these cases he said he presented them to emphasize the advantages of the rib-spreading operation in patients of this type. He had used this curved incision which Dr. Lilienthal advocated with the addition of an upper cut extending up to the seventh or sixth rib in nine cases and found it of distinct advantage where because of firm adhesions there was difficulty in reaching the apex of the empyema pocket. It enabled one to reach adhesions in both the anterior and posterior portions of lung. Another point to be taken into consideration was whether the patient would stand such a radical procedure at the first operation. If he could stand it it had an advantage in that it eliminated subsequent operations and permitted of drainage without the formation of adhesions.

Dr. HOWARD LILIENTHAL said he was very much pleased to see that Dr. Whipple had taken up the method, which he had been trying to popularize for some time. He thought he had solved, or nearly solved, the problem of chronic empyema when he came back from overseas, but he found that he had to begin all over again and work according to the method that Dr. Moschcowitz of the empyema commission had introduced, that was using the Carrel-Dakin solution and afterward trying to make an aseptic pneumothorax. Tuffier had first used this method and spoke well of it. It consisted in making a small resection for drainage and then using the Carrel-Dakin treatment. He could not in the limited time at his disposal go into all the details, but finally concluded to try the method, and a small series of cases was started in which the Carrel-Dakin treatment was given. Before using the Carrel-Dakin treatment he had had results with which he was perfectly satisfied; now he was having results that were not satisfactory. This was especially true in children, in whom the long period of drainage, which was absolutely necessary when this method was used, caused a deterioration in the general condition of the patient and often did a great deal of harm. In young, robust men following an attack of pneumonia all they had to do was to cure the empyema, and a week or a month longer of convalescence did not matter, so long as they were finally cured. In chronic empyema operated on as they had been doing before they began to use the Carrel-Dakin treatment the average time required for healing was about four weeks, seldom much longer, except in cases in which there was much thick exudate and old contracted lung. Since he had come back he had tried this Carrel method out very thoroughly, and he was on the point of going back to the old method which Dr. Whipple had demonstrated. But in this old method he always used the Carrel-Dakin treatment as an adjuvant after operation, as it kept the wound sterile and there it was of great value. In acute empyema, however, he was content to make a small incision between the ribs and by this procedure 25 or 30 per cent. of these cases would be cured without anything further, but they had to be checked up and examined by the *x*-ray and fluoroscope to see if they were progressing properly and if there was a reasonable expectation that cure would result quickly. If not, the radical operation should be done. In the last issue of the *State Journal of Medicine* he had reported the case of a young child with an almost complete pneumothorax which had healed up after a small resection. A year later the lung had filled the chest. He placed the greatest stress on the *x*-ray examination and did not believe an examination without the *x*-ray was worth much. He related that in 1913 he had met Professor Tuffier and had asked him how he regarded the *x*-ray and he replied that he held it to be of the greatest value and would be guided by the *x*-ray as against the physical examination. Of course physical examination had its place in diagnosis, but in the open chest the physical diagnosis was worth little. He cited an instance of a case seen in consultation after the chest was opened. The heart appeared to be far over in the axilla and it seemed that immediate operation was indicated. He expressed the opinion that the heart was in the normal position, though the pulsation appeared to be in the axilla; when the *x*-ray was taken in this case it showed the heart in the normal position. As to Dr. Whipple's technique, in addition to the use of the *x*-ray, he would suggest a little longer intercostal incision and the use of the rib spreaders which enabled one to see all parts of the chest, so that one did not need to rely upon the sense of touch. While the sense of touch revealed a great deal, the open operation with the use of the rib spreaders had the advantage of enabling one to see what he was doing, and often one found little holes that looked like dimples, but which led into secondary abscesses.

Dr. A. V. MOSCHCOWITZ said he did not wish to speak on the subject of empyema because he knew they would think that there was an absolute disagreement between Dr. Lilienthal and himself. While he was seeing very few cases of empyema at present he thought he was safe in saying that during the past two or three years he had seen 2500 cases of empyema. When he was called into the service there were 1,100 cases scattered through the camps and a year ago there were 1,100 cases. As a matter of fact, Dr. Lilienthal and he did not disagree to any great extent, only in a couple of minor points that looked like mountains, but were in reality only molehills. It was worth calling attention to the fact that Dr. Whipple's cases were all cases of acute empyema. He did not call a case one of true empyema unless there was thick purulent pus present. That day he had refused to operate on a child because there was merely a seropurulent fluid present, and he thought the child would get well without operation. In a number of cases if one made a short intercostal incision just sufficient to introduce one good sized drainage tube and gave them the Carrel-Dakin treatment they would make a rapid recovery. He had seen many use what they called the Carrel-Dakin treatment,but who were in reality using some John Smith modification of the Carrel-Dakin method and that was not the Carrel-Dakin treatment, and did not give the results of the Carrel-Dakin treatment. One might define a chronic empyema as that kind of an empyema which could not be sterilized with the Carrel-Dakin solution. If one could not sterilize a chronic empyema he should find out why, and sometimes he would find that this was because of a necrotic rib which could not be sterilized and which constantly fed the empyema cavity with infectious material. He had removed drainage tubes galore and sometimes had found pieces of gauze left in and other foreign bodies which did not permit of a sterilization of the empyema cavity. Of Dr. Whipple's cases two were due to the pneumococcus and were com-

paratively simple cases; the third case demonstrated just what they had found in the military service, and which were due to to the hemolytic streptococcus, during the hemolytic streptococcus epidemic, namely, that they were very bad cases indeed and lasted a much longer time than the pneumococcus infections. He had understood Dr. Lilienthal to say that as the soldiers with empyema were young, robust men it did not make so much difference if their empyemas were a long time in healing. He thought that by the time the soldiers came to operation after they had had pneumonia, or measles, or after a streptococcus pneumonia, they were very sick and their resistance greatly lowered. The early observations were followed by a high death rate; late observations recovered.

Dr. SEWARD ERDMANN stated that during the empyema epidemic of the fall of 1918 he had studied over 80 cases at an army camp in Michigan, where the Dakin solution was used in a more or less haphazard fashion, and although the results obtained were very fair and the mortality low, nevertheless a number of the cases lapsed into real chronic cases. Somewhat later in the winter he succeeded Dr. Moschcowitz at a Southern camp and was struck by the excellent results in a series of cases treated after Dr. Moschcowitz's plan with very careful adherence to the full Carrel-Dakin technique. In this series pus disappeared from the ward very promptly and most of the cases went on to an early and complete closure. Last spring and summer in a military hospital in Texas he had seen over a hundred cases, all of which were chronic, and represented the residual cases from other camps. Here, too, the full and careful application of Dakin solution succeeded in clearing up many of the very worst cases without resort to an extensive operation. However, it was true that in about 10 per cent. of the chronic cases sterilization of the old cavities was not attained, and in these cases an operation was indicated to break up adhesions which caused pockets and branching sinuses.

War Wounds of the Chest.—Dr. CHARLES GORDON HEYD read this paper, in which he said that all wounds of the chest were potentially infected. Modern surgery, however, was able to obviate, inhibit or prevent infection if the surgeon was able to operate during the golden period of operability—the first eight hours, preferably four, between the receipt of injury representing contamination and the development of infection which ordinarily became apparent about the eighth hour. The ideal operation contemplated (1) débridement of all soft tissue about the orifice of entry or exit, particularly all portions of contused, necrotic, or infiltrated tissue in or about the area of the wound; (2) the regularization of all bone ends; (3) complete esquillectomy or the removal of all bone fragments, particularly the indriven spicules of bone in the lung or pleural cavity; (4) the removal of the foreign body, unless smaller than the nail of the little finger; (5) a débridement of the traject in the lungs and if badly infiltrated or lacerated resection—partial or complete lobectomy; (6) adequate surgical and anatomical repair of the lung by suture; (7) complete toilet of the pleural cavity, removal of blood, foreign bodies, fragments of bone, portions of clothing, etc., many times lying free within the costophrenic sinus or impinging upon the chest wall; (8) repair of the diaphragm and such intraabdominal exploration as would seem indicated; (9) hermetical closure of the wound in the chest wall by any of the accepted methods. A satisfactory classification of war wounds of the thorax could be arranged as follows: 1. Perforating wounds, through and through, due to bullet. 2. Perforating wounds, through and through, due to shell fragment. 3. Penetrating wounds, with retention of large foreign body. 4. Penetrating wounds, with retention of small foreign body. 5. Tangential wounds. 6. Cave-in, stove-in or crushed-in chest. 7. Sucking wound or open thorax. 8. Combined abdominal or multiple wounds. In his own experience there were operatively proved injuries to the chest in 51 cases; gunshot wounds, 40, with 15 deaths; bullet, 4, with 1 death; undetermined, 7, with 2 deaths. The types of injury were perforating, 23; penetrating, 17; tangential, 2; cave-in, 2; thoracoabdominal, 7. The total mortality was 18. The mortality by type of injury was as follows: Tangential wounds, 2, with no deaths; perforating wounds, 23, with 6 deaths; penetrating wounds, 17, with 6 deaths; cave-in, 2, with 1 death; thoracoabdominal wounds, 7, with 5 deaths; admitted in pronounced shock, 19, with 8 deaths; admitted with sucking wound, 15, with 11 deaths; hemothorax, 28, with 12 deaths; hemopneumothorax, 5, with 2 deaths; the ribs were fractured in 18, with 8 deaths; the scapula, 6 times, with 4 deaths. The average duration between injury and arrival at the hospital was 19 hours, the earliest time being 4 hours and the longest time 96 hours. A summary of the surgical indications for operative intervention could be tabulated as follows: (1.) The closure of sucking wounds of the chest wall irrespective as to the retained foreign body or the mechanism of production of the injury. (2) Continued bleeding or unusual hemorrhage. (3) Grossly infected contused or contaminated wounds of the soft tissues. This variety eliminated the cases with a clean cut rifle bullet wound or the penetrating type of wound due to small shell fragment. (4) Wounds with fracture of the ribs, clavicle, scapula or vertebra complicating the original or primary injury. (5) The retention of foreign bodies other than small éclat. By small he meant a shell fragment certainly not larger than the nail of the little finger. (6) The onset of a progressive hemopneumothorax. (7) Stove-in or crushed-in chest with multiple fractures of many ribs whereby the bone ends protruded into the pleural cavity, bringing about a laceration of the lungs. In wounds in the scapular region, perforating high up between the vertebral column and the scapula, it was rather difficult to obtain adequate access to the pleural cavity. Trephining the scapula proved a very unsatisfactory procedure and excision a needless loss of bone substance. It was much better to divide the rhomboid muscles, the serratus magnus and the latissmus dorsi at the lower angle of the scapula and throw the scapula upward and outward. If the nature of the wound would permit resection of the fourth or fifth rib was carried out from the midscapular line upward to the posterior axillary line. Where an injury was low down with compound fracture of the sixth, seventh, or eighth rib in the midaxillary region, then the incision was enlarged by resecting the seventh rib. Through such an incision the pericardium was sutured twice and in another case a large transdiaphragmatic hernia was replaced with ease. When the diaphragm was injured well out in the costophrenic sinus the central portion was occasionally sutured to the parietal pleura. This technique was only employed in combined thoracoabdominal cases and where it was essential to close the pleural cavity and at the same time insert gauze into the renal fossa or into the liver. Rarely a loss of substance of the diaphragm could more easily be repaired by suturing the lacerated edge to the parietal pleura than by closure of the defect.

Dr. WILLY MEYER said we all had followed those who had worked immediately behind the fighting lines with the keenest admiration, and that what they had accomplished would stand forever in the annals of war surgery. Those who had not been abroad, at least had had the benefit of watching the successes and failures of those who were doing the work. He believed that in order to make progress in thoracic surgery we would have to come to the point of laying down the principles that governed our work. The wounds of peace were the same as those of war, except that the victim of traumatic injury could be cared for immediately and, therefore, acute infection was absent in the majority of cases at the time the surgeon could take hold of the patient. Dr. Heyd had described methods somewhat different from those surgeons had been using in civil practice, and naturally so. The surgical war work was done under stress, and was emergency work. Now that we were back in peace we could and had to do the best that science offered for our patients. Personally he believed that adherence to the principles on the basis of which surgeons had worked in peace times was absolutely necessary for the further safe evolution of this chapter of surgery, and those principles required in the first place preparation for the use of differential pressure. Secondly, "airtight thoracic drainage," as a routine measure, ought to be generally accepted. In case of internal hemorrhage one would, of course, open the chest and try to stop the bleeding. Many would then close the wound and watch the patient. He preferred, in every instance of thoracotomy, to close the incision

completely and add airtight drainage. This would guard against the otherwise frequently occurring pleural exudate. Furthermore, the lung would have the chance of immediate distension.

Dr. CLARENCE A. MCWILLIAMS said that the indications for operation depended somewhat upon the type of anesthesia that was available. If one had simply ether it was better to be conservative. In his opinion the perforating through and through bullet wounds should not be operated upon. Sucking wounds, excessive hemorrhage, and sepsis required operation, but there was a middle class of cases in which the question whether to operate or not was a debatable question. If gas-oxygen was available (and he hoped in the next war apparatus for administering gas-oxygen would be supplied to every hospital) one could operate on cases in which one could not expect satisfactory results under ether anesthesia, because with gas-oxygen excellent expansion of the lungs could be obtained with the chest opened, and this diminished shock considerably. During the last year of the war English and French surgeons found sucking wounds of the chest were best treated by the first aid surgeon on the field when met by sewing up the wound by a string and needle without regard to asepsis. This could be attended to when the man reached the aid station or evacuation hospital, where a further procedure was undertaken which perhaps proved lifesaving. At La Foret they had perhaps 80 cases of chest wounds at one time which they had not operated upon, and when Dr. Brewer saw them he expressed surprise that they were doing so well. The treatment was morphine, strapping, and tapping if the hemothorax became distressing. In radical chest surgery the mortality was greater than among those more conservatively treated. He knew that chest surgery was a very much discussed subject, with the opinions varying with the operator *pro* or *con* operation. He had seen some radical chest surgery back of the lines that he considered a reproach to surgery.

Dr. MCCREERY said that the men in different hospitals and clearing stations had very different ways of treating chest wounds. He thought the best mortality records were among the cases treated conservatively.

Dr. HOWARD LILIENTHAL said that he agreed perfectly that perforating machine gun wounds ought not to be operated upon except for complications, but high explosives, causing splintering of the ribs, had to be operated upon or else very serious complications arose. Where the ribs were splintered, spiculæ of bone might turn into the lung and had to be removed or they caused further laceration of the lung tissue with every respiration. In such cases one should make a good-sized incision and put in the rib spreader, for otherwise he could not tell just what the conditions were. In order to do that work and do it right it was necessary to have intrapharyngeal differential pressure. He had taken with him when he went over a simple apparatus for this purpose, consisting of a small foot bellows and an ether bottle with a three-way cock in the stopper. With this one could safely inflate or collapse the lung. The operation of this apparatus was simple. He had taught a nurse to use it under supervision with only one lesson. A method not mentioned by Dr. Heyd was that of closing large pleural defects by inflating the lung until it came to the surface and then sewing it in the opening as a plug. He had just heard the day before from a boy who had had a hole in his chest wall as large as a silver dollar. He had made a complete recovery both as regarded his physical condition and the physics of his lungs. In this case, even though the lung had later pulled away from the opening, a good recovery had followed. He was not the only one who had used differential pressure on the other side. Dr. Yates had also used it, but in a different way, with nitrous oxide gas.

Dr. H. H. M. LYLE said that it was extremely difficult to get accurate figures on the mortality of wounds of the chest; but one thing he was certain of was that it was much higher than we had been led to believe. A very large number of men died of chest wounds on the battlefield in the Meuse-Argonne offensive. Dr. Lyle had examined men who had fallen in front of machine guns and found that a large percentage of them had been shot through the lung. It was impossible, of course, to get a battlefield mortality, but the combined mortality from the dressing station back to the base hospital is between 45 per cent. and 50 per cent. The further one got away from the line the lower the death rate. One of the speakers had spoken of the bullet wounds of the chest. A perforating bullet wound of the chest, if it did not hit a vital structure, or a rib, gave a mortality of about five per cent. or less. In such cases the expectant treatment was justified, and no one now thought of operating upon these cases. But it was incorrect to draw broad conclusions from a certain type of wound and apply them to all wounds. Dr. Lyle had seen the progress of lung surgery since 1915 in base, evacuation, and front line hospitals, and he was firmly convinced that the operative treatment of the suitable cases had materially cut down the mortality and diminished the complications. Regarding sucking wounds of the chest, it was interesting to note that Baron Larrey had advocated and successfully practised the closure of such wounds one hundred years ago. Differential pressure was an aid in doing the work, but by no means a necessity. In fact, one of the best series of cases known to Dr. Lyle was done under ordinary anesthesia. The necessities were a good localization, a good exposure, the removal of the projectile, a good débridement, and a good closure of the chest. Dr. Lyle said he felt, with Dr. Heyd, that, if a piece of high explosive were lodged in his chest, he would take his chance with an operation, for he would realize that he would have a 20 to 25 per cent. better chance in the hands of a good surgeon than if left alone.

Dr. ALBERT S. MORROW said that he had had some experience with chest wounds at Evacuation Hospital No. 2, where they had a number of these cases to operate on. There was no questions as to what should be done with through and through wounds made by a small rifle; they did well if left alone. If there was considerable hemothorax it sometimes embarrassed the heart. If in such cases they waited from twenty-four to forty-eight hours and then aspirated there was little danger of a further collection of blood. As to the penetrating wounds, they operated on all of them irrespective of whether they were sucking or not, provided there was a foreign body in the chest of a size that they were reasonably certain to be able to find and extract, just as they would do in soft parts elsewhere in the body. It was, however, more important to remove a foreign body from the lungs, because it not only carried with it the dirt, shreds of clothing, etc., that it did elsewhere, but also splinters of rib, and as a consequence one sometimes got late complications. They made a wide intercostal incision, used the rib spreaders to get a good exposure, removed the foreign body, and sewed up the lung. They had had between 75 and 80 per cent. recoveries among the cases operated upon.

Dr. HEYD, in closing, said there was no question but that in ordinary cases every one knew when operation was indicated. He said he was at La Foret with Dr. Yates and Dr. Lyle, where the cases were coming in thirty hours after they had been injured. When a patient came in that long after injury and sat about and smoked and appeared fairly comfortable they felt that if he had lived that long he was going to get well. At a distance of four miles behind the front line the situation was entirely different from what it was at ten miles back of the fighting line, and as they continued to go back the conditions were still different. He was convinced that if he were wounded in the chest and had a retained foreign body larger than his little finger nail he would want to be operated on at the earliest opportunity.

A New Technique for Gastrectomy.—Dr. A. L. SORESI gave a lantern slide demonstration of a new technique for a gastrectomy, reconstructing the anatomical and physiological relations between the stomach and intestine, which consisted in a modified Roux operation. By this method the gastroenterostomy was made between the stomach and the jejunum. A particular point in the technique was a through-and-through suture, which was the same on both the anterior and posterior aspects of the gastroenterostomy opening.

Dr. SORESI also presented three new instruments: (1) a forceps for grasping and emptying the gallbladder; (2) a device for pneumatic hemostasis, consisting of

rubber balls and bags of various sizes with which the bloodvessels were compressed; (3) a needle and holder for wire suture.

Dr. GEORGE WOOLSEY said he had never liked to use Payr's clamps on the side of the incision that was going to remain, because owing to the trauma that was inflicted it left a slough that had to be avoided in suturing. As to the through-and-through sutures, he did not see that they were different from those he had been using in gastroenterostomies, on the posterior aspect, though he changed the stitch when he came on to the anterior aspect. As to the use of the jejunum, suturing it in this way into the stomach it was a method he had never used. He had, however, seen a case last summer in which Roux's operation, very similar to the method, was used and the results were bad. He did not see how this procedure could shorten the time over that required by other methods, like the Polya operation. It seemed, however, to give good results so far as the anatomical relations were concerned.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO BOARD OF MEDICAL EXAMINERS.

Denver, October 7, 1919.

(*Continued from page 298.*)

TOXICOLOGY.

1. Classify poisons and give action and example of each.
2. Describe carbolic acid poisoning, give antidote and treatment.
3. Give symptoms, antidote, and treatment for strychnine poisoning.
4. Give symptoms arising from toxic doses of digitalis. Give treatment.
5. Describe poisoning by wood alcohol. What are the bad effects resulting from such poisoning in non-fatal cases?
6. Describe opium poisoning. Give symptoms and treatment.
7. Give symptoms of poisoning by illuminating gas. What reaction takes place in the blood?
8. Describe forms of ergot poisoning.
9. Describe case of lye poisoning. Give treatment.
10. Name five vegetable poisons not mentioned in the above questions. Give symptoms and treatment for one.

PATHOLOGY.

1. Describe in detail post-mortem examination of the brain.
2. Define atrophy with varieties.
3. Discuss (*a*) fatty degeneration; (*b*) edema; (*c*) amyloid degeneration.
4. Define (*a*) anemia with varieties; (*b*) hyperemia; (*c*) leucemia, varieties and significance.
5. Define infarction. Where does it occur most frequently?
6. Define (*a*) catarrhal inflammation; (*b*) infective inflammation; (*c*) suppurative inflammation; (*d*) plastic inflammation.
7. Name types of gangrene, giving conditions determining each.
8. Differentiate histologically sarcoma and carcinoma. Name the types of sarcoma and carcinoma in the order of their malignancy.
9. Describe the appearance of the heart in an advanced case of mitral stenosis; its effect on other organs, and tell how it is produced.
10. Name varieties of urinary renal casts. Give characteristics of each, and state of what forms of renal disease each is a part.

SYMPTOMATOLOGY.

1. Differentiate embolism and thrombosis.
2. Discuss influenza, giving etiology, course, and complications.
3. (*a*) What is the most usual valvular lesion? (*b*) Give cause and physical signs of same.
4. Give a diagnosis of pneumonia, differentiating it from other pulmonary conditions.
5. (*a*) What is the sphygmomanometer? (*b*) What significance have its findings? Illustrate.
6. Differentiate the exanthemata.
7. Define Kernig's sign and give its significance.
8. What symptoms would lead you to suspect syphilis? How would you proceed to verify your suspicions?
9. Give diagnosis, course, cause, and complications of gastric ulcer.
10. Give diagnosis, etiology, and complications of pyelitis.

ANSWERS.

TOXICOLOGY.

1. *Classification of Poisons.*—There are many classifications given, but not one of them is entirely satisfactory. The following is Taylor's: Poisons are divided into (1) Irritants, and (2) Neurotics.

Irritants are subdivided:

Mineral.
Acid poisons—Sulphuric acid.
Alkaline poisons—Caustic soda.
Non-metallic—Phosphorus, Iodine.
Metallic—Arsenic, Antimony.

Vegetable.
Savine, Elaterium.

Animal.
Cantharides.

Neurotics are subdivided:

Cerebral—Opium, Alcohol.
Spinal—Strychnine.
Cerebrospinal—Aconite, Belladonna.
Cerebro-cardiac—Digitalis.

2. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The *treatment* consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal. At one time alcohol was much used; just now the older remedies (such as sodium sulphate) are more relied on. Soluble sulphates form with carbolic acid the insoluble sulphocarbolates, which can be removed by lavage.

3. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms(usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment.—"The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

Solution of potassium permanganate is now believed to be the chemical antidote.

4. *Symptoms of poisoning by digitalis:* "Nausea, and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours, marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient. Death is generally by syncope, sometimes after several hours of coma succeeded by convulsions. *Treatment:* The patient must be kept strictly in the recumbent position. The stomach should be washed out with infusion of tea by the stomach tube. Stimulants should be given."—(Witthaus' *Essentials of Chemistry.*)

5. *Symptoms of poisoning by wood alcohol.*—"These begin with gastrointestinal disturbance, abdominal pain, general weakness, nausea, vomiting, vertigo, headache. The symptoms of ordinary alcoholic intoxi-

cation supervene, with delirium, restlessness, unconsciousness, collapse and coma. The pupils are usually dilated and irresponsive; nystagmus may be present. Dyspnea and cyanosis are marked. The temperature is subnormal."—(Sollman's *Pharmacology*). *The usual bad effect in non-fatal cases* is blindness following retinitis and retrobulbar neuritis.

6. The *symptoms of poisoning by opium* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis, the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."—(Witthaus' *Essentials of Chemistry and Toxicology.*)

Treatment of opium poisoning consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment to keep the patient awake; artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter.

7. In *poisoning by illuminating gas*, the symptoms are those of poisoning by carbon monoxide: Dizziness, headache, mental confusion, weakness, nausea, vomiting, convulsions, unconsciousness, livid face and dilated pupils.

In the blood, the carbon monoxide unites with the hemoglobin making a stable compound; this prevents the hemoglobin from carrying oxygen to the tissues. The blood is of a cherry red color, and on spectroscopic examination it shows a characteristic absorption band.

8. *Acute ergotism:* "In a large dose ergot acts as a gastrointestinal irritant, causing nausea and vomiting, gastralgia, colic, thirst, and purging. It slows the heart, raises the arterial tension greatly, dilates the pupils and produces pallor, vertigo and frontal headache. It stimulates the contraction of unstriped muscular fiber, especially affecting the sphincters and causing contraction of the sphincter of the bladder, making micturition difficult if not impossible. It produces cerebral and spinal anemia, a great fall of the body temperature, coldness of the surface, tetanic spasms, and violent convulsions." *Chronic ergotism* "occurs in two forms, the convulsive and the gangrenous—either usually excluding the other. The convulsions are tetanoid spasms of the flexor muscles, the uterus, the intestinal fibers, and the muscles of respiration, ending in coma and death by asphyxia. The gangrenous form begins with coldness and numbness of the limbs; formication of the skin all over the body, loss of sensibility and abolishment of the special senses, bullæ of blood and ichor, followed by dry or moist gangrene of the lower extremities, buttocks, and other parts, epileptiform convulsions, coma, and death. Autopsies show changes in the posterior columns of the cord, resulting probably from spinal anemia."—(Potter's *Materia Medica*, etc.)

9. *Effects of concentrated lye poisoning:* "A nauseous acrid taste, rapid destruction of the mucous membranes and even the deeper tissues of the mouth and throat, burning pain in the throat and stomach extending very soon to the abdomen, which becomes exceedingly tender, aphonia, vomiting of bloody mucus, frothy and with a soapy taste, pulse small and thready, surface cold and covered with a clammy perspiration, great prostration, sometimes ending with convulsions, especially with children. When potassium hydroxide has been taken it sometimes shows its specific action on the heart, causing slow, weak pulse, the patient sinking into unconsciousness. Constipation is sometimes troublesome, but generally a bloody diarrhea supervenes. The urine is scanty and alkaline, or entirely suppressed. The blood is dark and gelatinous. If the patient survives a few days, sloughing of the fauces and esophagus may occur, followed by stricture and death from exhaustion or starvation, or the stomach may have been most severely affected and death result from destruction of its functions."—(Riley's *Toxicology.*)

10. *Five vegetable poisons:* Aconite, belladonna, cocaine, stramonium, colchicum.

"*The symptoms of poisoning by aconite* usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

"The *treatment* should be directed to the removal of the unabsorbed poison by the stomach tube, and washing out of the stomach with infusion of tea holding powdered charcoal in suspension. Stimulants should be freely administered."—(Witthaus' *Essentials of Chemistry.*)

PATHOLOGY.

1. *Post mortem examination of the brain:* "*To examine the brain* place it on its vertex with cerebellum toward one. The pia and the cranial nerves should be examined. Then carefully note the arteries for changes in size, malformations, presence of atheroma, aneurysms, or of tubercles. Separate the Sylvian fissure and examine the vessels there as tubercles, emboli, aneurysms, and hemorrhage may be discovered although absent elsewhere. To *section the brain* the following method is generally employed: The brain is placed on its base and the hemispheres separated till the corpus callosum is exposed. The first incision is made into the lateral ventricle about 3 mm. from the median line of the corpus callosum and extending into the anterior and posterior cornua. Posteriorly the convolutions over the cornua are cut through. A series of incisions are made through the hemisphere just external to the basal ganglia with their edges coinciding but going at an angle of about 45 degrees. This gives a number of wedge-shaped portions, held together by the pia, which should not have been removed. The brain is turned half around and the process repeated on the other side. Care must be taken not to injure the ganglia when opening the ventricle. The *corpus callosum* is gently lifted and divided by passing a knife through the foramen of Monro and cutting from below upward. The cut portions are reflected, exposing the velum interpositum and the choroid plexus. The *third ventricle* is disclosed by drawing back the velum interpositum. The *vermiform process* is cut through, opening the fourth ventricle; the aqueduct is cut and all the ventricles are exposed. The *corpora quadrigemina* are found by dividing the right posterior pillar of the fornix and reflecting it to the left. The *basal ganglia* are exposed by making a series of transverse cuts, the brain being supported from below by the left hand. The *pons* and *medulla* are cut transversely into thin sections. The *cerebellum* is divided along the median line into two halves, each of which is subdivided by a series of incisions at right angles to the primary cut."—(McConnell's *Manual of Pathology.*)

2. *Atrophy* is a decrease in the amount of tissue, owing to a diminution of the histological elements of which it is composed; if this diminution is in the *size* of these elements it is called *simple atrophy;* if the diminution is in the *number* of these constituent elements it is called *numerical atrophy.*

3. In *fatty degeneration* there is an accumulation of fat in the cells of a tissue or organ; it is assumed by many that the protoplasm of the cell is converted into fat; in this way it is differentiated from fatty infiltration, in which the fat is brought to the cell from outside, and the cell is only inconvenienced mechanically. In fatty degeneration the function of the cell is apt to be greatly impaired.

Edema is an accumulation of a watery fluid within

the tissues, and between the cells. Numerous factors have been assigned as the cause of edema, viz.: Increased pressure in the blood vessels, increased permeability of the walls of the blood vessels, osmosis, selective action of the endothelium, and tendency of colloid bodies to take up water.

Amyloid degeneration is a degeneration of the connective tissues into a waxy, lardaceous material which gives the amyloid reaction. It occurs in cases of long continued suppuration, bone diseases, etc., and the organs most commonly affected are the spleen, liver, and kidneys.

4. *Anemia* is a condition characterized by a diminution in the number of red-blood cells, or of hemoglobin, or of both.

Varieties: (1) Local.

(2) General { Primary { Chlorosis. / Pernicious anemia. / Secondary

In *secondary anemia*, the blood would show: (1) A diminution in the number of red corpuscles; (2) a diminution in the amount of hemoglobin, perhaps greater than that of the red corpuscles; (3) poikilocytosis, and variations in the size of the red corpuscles; (4) the presence of a few nucleated red corpuscles; (5) a moderate leucocytosis.

In *pernicious anemia* the blood would show: (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes *may be* diminished.

In *chlorosis*, the blood shows: (1) A great diminution in the amount of hemoglobin; (2) a slight diminution in the number of red corpuscles; (3) poikilocytosis; (4) occasionally a few nucleated red corpuscles; (5) a very slight leucocytosis.

Hyperemia is a general increase in the total amount of blood in the body. It may be (1) active, or arterial; and (2) passive or venous.

Leukemia is a condition in which there is a great and persistent increase in the number of white blood corpuscles. There are two varieties of the disease: (1) *Splenomedullary* in which the chief changes are found in the spleen and bone marrow; and (2) *lymphatic*, in which the chief changes occur in the lymphatic glands. In *splenomedullary leukemia*, there is an enormous leucocytosis, and myelocytes are present. In *lymphatic leukemia*, the lymphocytes form the main part of the leucocytosis, and there are no myelocytes.

5. *Infarction* is a process of degeneration and inflammation occurring in a tissue or organ as the result of an embolism in an end-artery. It occurs most frequently in the spleen, kidneys, brain, and lungs.

6. A *catarrhal inflammation* is one affecting a mucous membrane and in which the increased blood supply causes an increased flow of mucus.

An *infective inflammation* is one which is caused by microorganisms.

A *suppurative inflammation* is one charatcerized by a mucopurulent discharge.

A *plastic inflammation* is one in which there is an exudation which glues together adjacent surfaces.

7. TYPES OF GANGRENE: *Dry gangrene*, in which the arterial blood supply is cut off or decreased. *Moist gangrene*, in which there is also interference with the venous return from the part. *Microbic gangrene*, in which the gangrene is caused by virulent microbic invasion. *Senile gangrene*, which is due to feeble heart action and endarteritis obliterans, or atheroma of the peripheral vessels. *Gaseous gangrene*, which is due to virulent infection which is either of a mixed type or is due to the bacillus of malignant edema or bacillus ærogenes capsulatus. *Raynaud's gangrene* is a vasomotor neurosis.

8.

SARCOMA.	CARCINOMA.
Origin; entirely mesoblastic. (Connective-tissue type).	Epiblastic and hypoblastic (Epithelial-tissue type).
Stroma; intercellular. Rarely forms alveoli.	Vascular connective tissue, which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
Cells; granulation tissue or embryonic connective-tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
Intercellular substance; may be present.	Absent, or merely fluid.
Vessels; embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective tissue stroma, and supported by the walls of the alveoli. Seldom in contact with the cells.

—(From Coplin's *Pathology.*)

MALIGNANCY. Of the *sarcomata*, the soft round-celled and large spindle-celled varieties are more malignant than the small spindle-celled tumors; myeloid sarcoma is the least malignant. Of the *carcinomata*, encephaloid is more malignant than scirrhus; epithelioma is the least malignant.

9. "In *mitral stenosis* there is an increase in the intra-auricular pressure toward the end of auricular diastole, due to the blood from the lungs flowing into an insufficiently emptied auricle; the consequent dilatation and stretching excite the auricle to very vigorous contractions, which become augmented in consequence of the obstruction to the discharge of blood. The result is an extraordinary enlargement (hypertrophy and dilatation) of the left auricle, which may attain dimensions three or four times the normal. Increased intrapulmonary pressure is followed by hypertrophy and dilatation of the right ventricle, which as in mitral insufficiency is the efficient factor in maintaining compensation. In some cases, for a time at least, the increased power of the left auricle serves to supply a normal amount of blood to the left ventricle, which in consequence presents no noteworthy deviations from the normal. In many cases, however, on account of associated mitral insufficiency, the left ventricle is somewhat enlarged; in most cases the amount of blood supplied to the left ventricle is less than normal, in consequence of which it is often said to become reduced in size (this is more apparent than real)."—(Kelly's *Practice of Medicine.*)

"When compensation fails the various organs of the body suffer congestion. The lungs are first affected in disease of the left heart (mitral and aortic disease). The capillaries of the pulmonary alveoli become over full and encroach upon the lumen of the alveoli, or by elongation stretch the alveolar walls and render them inelastic. In either case proper respiration is prevented —a condition which is further aided by the retarded pulmonary circulation. As a result of these conditions, dyspnea (cardiac asthma), cough, and expectoration develop. In extreme cases edematous exudation takes place, and in long-continued cases cyanotic induration of the lung occurs. In such instances there may be continuous cough and respiratory insufficiency. When the right heart fails, the liver, spleen, gastro-intestinal mucosa, the kidneys, and the peripheral circulation suffer congestion. The liver may become greatly engorged, and in certain cases actually pulsates with each ventricular systole. The swollen liver-cells and the engorged vessels cause obstruction of the biliary capillaries, and consequently produce jaundice. To some extent this may be due to associated congestion of the biliary channels. Congestion of the gastro-intestinal mucosa may occasion various forms of gastric or intestinal derangement."—(Stengel's *Pathology.*)

10. "*Renal casts*" are cylinders of albuminoid substances formed in the uriniferous tubules. They are often composed in part of epithelial cells, blood cells, or the products of degenerated cells. They appear as: (1) *Hyaline casts.* These are clear, translucent cyl-

inders, often so pale as to be scarcely visible. They occur in the urine in all forms of nephritis, in congestion of the kidneys, in jaundice, and even in health. They are frequently the only casts present in chronic interstitial nephritis. (2) *Waxy casts.* These resemble hyaline casts, but they appear more solid and rigid and are more or less yellow. They occur especially in chronic parenchymatous nephritis. (3) *Epithelial casts.* These are cylinders of epithelial cells or hyaline casts covered with epithelial cells. They occur especially in acute parenchymatous nephritis. (4) *Granular casts.* These are cylinders covered with the débris of broken-down epithelial cells. They may occur in any form of nephritis. (5) *Fatty casts.* These are casts studded with oil-drops derived from degenerated epithelium. They occur chiefly in chronic parenchymatous nephritis. (6) *Blood casts.* These are cylindric masses of red blood cells, or, more commonly, hyaline casts studded with red blood cells. They occur in acute and chronic hemorrhagic nephritis. (7) *Pus and bacterial casts.* Casts composed respectively of masses of pus cells and of bacteria are occasionally met with in suppurative nephritis. (8) *Cylindroids.* These formations may resemble hyaline casts, but they are usually much longer and often taper off at one end to a thread. Moreover, they frequently show constrictions at different points. Their presence is not a proof of nephritis. They often occur in conditions of renal irritation."—(Stevens' *Practice of Medicine.*)

10. SYMPTOMATOLOGY.

CEREBRAL EMBOLISM.	CEREBRAL THROMBOSIS.
Causes.—Most commonly associated with valvular lesions of the heart, aneurysms, or a suppurating thrombus.	*Causes.*—1. Arteriosclerosis, atheroma, and syphilitic disease of the arteries. Bright's disease and alcoholism therefore predispose. 2. Pressure upon the veins or arteries (tumor or abscess).
Age.—Chiefly in young adults.	*Age.*—In the old from vascular degeneration; in the young from syphilis.
Onset.—Sudden—no prodromal symptoms.	*Onset.* — Gradual — with prodromal symptoms.
Convulsions.—Rare.	*Convulsions.* — Convulsive attacks are not uncommon, as the cortex is frequently affected.
Paralysis. — A sudden hemiplegia of the right side *with aphasia.* The left middle cerebral artery is most frequently plugged.	*Paralysis.* — Paralysis is more gradual. Aphasia is not so common, as either the right or left side may suffer.
Consciousness.—Not *usually entirely* abolished.	*Consciousness.*—Often not lost. Coma may come on gradually, after the hemiplegia.

—(From Wheeler and Jack's *Practice of Medicine.*)

2. *Influenza.* The late epidemic has modified previous ideas on the subject. At any rate, the cases seen in the late epidemic did not conform to those seen in previous epidemics, or to the general textbook descriptions. *Etiology:* The following microorganisms have been credited with causing the disease: Pneumococcus, Streptococcus hæmolyticus, Streptococcus viridans, Staphylococci, Bacillus mucosus capsulatus, Bacillus influenzæ. *Course:* Many cases were of sudden onset; some were ushered in by a slight sore throat, or general malaise; the body temperature showed a rapid rise, going to 100 to 104° Fahr., or more; headache, severe pains in joints and muscles and back; great weakness, chilly sensations, alternating with hot spells; cyanosis, or flushing of face, and partial stupor were noted in most cases. Later, symptoms of bronchitis, bronchopneumonia, or lobar pneumonia developed. Following the disease, the patient complained of intense weakness, fatigue, and profuse sweating. The chief *complications* were pneumonia, bronchopneumonia, bronchitis, and various nervous disturbances.

3. The most usual valvular lesion is mitral regurgitation. Most cases of chronic endocarditis are the result of an acute endocarditis following rheumatism, infectious, or other diseases.

PHYSICAL SIGNS OF MITRAL REGURGITATION. "*Inspection* shows displacement of the apex beat downward and to the left. In children and youths, bulging of the precordium and increased cardiac impulse are present. In emaciated individuals, an auricular impulse may be observed to the left of the pulmonic area in the second interspace. *Palpation* serves to confirm inspection. The displaced cardiac impulse is forcible and diffused in the early stage; as compensation fails, the impulse becomes feeble or absent. *Percussion* shows an increase in the area of cardiac dullness transversely and vertically. *Auscultation* reveals a systolic or blowing murmur, heard best in the mitral area and transmitted to the apex, left axilla, and under the angle of the scapula. It may occur with or take the place of the first sound of the heart, the second sound being markedly accentuated, particularly in the pulmonic area."—(Hughes' *Practice of Medicine.*)

4. *Pneumonia* (*lobar*) is diagnosed by the physical signs as follows: "*Inspection* reveals during the first stage deficient movement of the affected side, due to pain. The apex beat is normal in situation, and the interspaces do not bulge. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air, the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation* during the first stage shows the vocal fremitus to be more distinct than normal, especially over the diseased portions. In the second stage, the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion:* In the first stage, the percussion note is slightly impaired at times, having a hollow or tympanitic quality. In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining areas the resonance is increased (Skoda's resonance). *Auscultation:* In the first stage there is heard over the affected part a feeble vesicular murmur, associated with the true vesicular or crepitant (crackling) râle, heard at the end of inspiration only. In the second stage there is harsh, high-pitched, bronchial respiration, at times resembling a to-and-fro metallic sound, except in those rare instances in which the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present, and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage, the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitatio redux) returns. As resolution proceeds the breath sounds are associated with large and small moist and bubbling râles.—(Hughes' *Practice of Medicine.*)

PLEURISY WITH EFFUSION.	LOBAR PNEUMONIA.
Onset marked by chilliness persisting for a few days.	Onset acute, with rigor, lasting one hour or longer.
Cough is irritating; no expectoration, or, if present, catarrhal in character.	Cough more marked, and accompanied by rusty or bloody, tenacious expectoration.
Sputum negative; tubercle bacilli rare.	Dense aggregation of pneumococci present.
Moderate fever of continuous type; declines by lysis.	Fever, 102° to 104° F.; falls by crisis.
Prostration moderate.	Prostration extreme.
Unilateral distension of the thorax.	Absent.
Countenance pale and anxious.	Mahogany-colored flush of cheeks.
Limited expansion at base of chest on the affected side.	Degree of expansion slightly, if at all, inhibited.
Tactile fremitus diminished or absent.	Increased over area of consolidation.

PLEURISY WITH EFFUSION.	LOBAR PNEUMONIA.
Interspaces bulging at base of chest.	Absent.
Percussion shows flatness, with great resistance to the plexiometer finger.	Dullness with less resistance, and sometimes a tympanitic note.
Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by râles. Bronchial breathing may be present over the entire affected side of the chest.	Harsh bronchial breathing and presence of râles in first and third stages, unless a bronchus is plugged.
Friction sound heard in early and late stages.	No friction murmur; râles present.

Edema of the lungs may be confounded with the first stage of pneumonia, but the subsequent history, its presence on both sides, and the waterish expectoration and absence of chill and pain, and the physical signs of pneumonia soon determine the diagnosis.

Typhoid fever, when accompanied by hypostatic congestion of the lungs, may be mistaken for pneumonia; the history, mode of onset temperature record, Widal reaction, etc., will aid in making the correct diagnosis. Hypostatic congestion occurs late in typhoid, while pulmonary congestion is the earliest manifestation in pneumonia.

Acute phthisis may resemble the affection closely, and is only differentiated with certainty by finding the tubercle bacillus in the sputum.

5. The *Sphygmomanometer* is an instrument for the determination of blood-pressure. *Pathological High Blood-Pressure.*—"High pressure *per se* is not a disease but a phenomenon, or symptom, which may accompany a great variety of diseased conditions, including diabetes, gout, syphilis, chronic lead poisoning, cardiovascular renal disease, many anomalies of nutrition, etc. *Acute Asphyxia and Acute Anemia* of the brain (medullary centers) will powerfully stimulate the vasomotors, causing contraction of the splanchnic area and a rise in blood-pressure. *Lead colic* affecting the abdominal vessels is usually associated with high blood-pressure, as is also the early stage of peritonitis. *Pain*, even when slight, as in pinching the skin, usually elevates pressure. Continuous high pressure is seen in certain forms of nephritis. Thus in primary acute Bright's disease and in nephritis secondary to scarlet fever, there is practically always a marked rise in arterial pressure. A rise amounting to more than 50 millimeters Hg. has been observed within 48 hours of the onset of an acute nephritis. Elevated pressure is also found in beginning arteriosclerosis of the first part of the aorta and of the splanchnic vessels."

Pathological Low Pressure.—"A pathological depression in blood-pressure may be caused by the depressing influence of circulating toxins, action either upon the heart, blood-vessels or controlling nervous mechanism, or to sudden withdrawal of a large volume of blood from the circulation as in hemorrhage, after *venesection, copious diaphoresis, diarrhea*, or in *shock*. In general it may be said that lowered blood-pressure is of little significance except after hemorrhage or during surgical shock. Here the great and sudden reduction in pressure may be sufficient to immediately endanger life. It is noted that a moderate and progressive falling pressure occurs in most progressive and prolonged fevers, as in typhoid fever. When due to such a cause the depression is rapidly overcome and disappears as convalescence is established. Widespread dilatation of the vessels and consequent lowering of blood-pressure has been noted in the last stages of *arteriosclerosis*. (Krehl.)"—(Faught's *Laboratory Diagnosis.*)

7. *Kernig's sign.*—Flex the thighs upon the abdomen and the legs upon the thighs; if the patient has meningitis he is unable to extend the legs, owing to contraction of the hamstring muscles. It is a most important sign in the diagnosis of cerebrospinal meningitis, being present in about 90 per cent. of cases; but it may also be found in other conditions such as sciatica, hip joint disease, and knee joint disease.

6. Differential Diagnosis of the Exanthemata.

Name.	Period of Incubation.	Stage of Invasion.	Time of Appearance of Eruption.	Character of Eruption.	Duration of Eruption.	Location.
Cerebrospinal meningitis.	Unknown	Sudden	2d to 4th day.	Herpes labialis, purpuric spots, dusky erythema.	.....	Herpes on lips; purpuric spots over entire body.
Erysipelas	Few hours to 3 or 4 days.	1 to 3 days.	Within 24 hours.	Efflorescence; bright-red; polished; with well-defined, raised margin.	4 to 8 days.	Face.
Measles	10 to 12 days.	4 days.	4th day.	Papules; small, dark-red, with crescentic borders. Complete in 24 hours.	4 to 5 days.	Face; then downward over body.
Rotheln	8 to 17 days.	24 to 48 hours.	Within 48 hours.	Macules; rose-red; rounded; discrete.	3 days.	Face and scalp; then downward over body.
Scarlatina	1 to 21 days.	1 to 2 days.	Within 24 hours.	Diffuse; scarlet; punctate.	7 to 10 days.	Neck, chest, face; then over body.
Typhoid fever.	5 to 35 days.	6 to 8 days.	7th day.	In crops. Rose-colored lenticular spots.	Each crop 3 to 5 days; lasts 10 to 20 days or throughout the whole course of the fever.	Abdomen, chest, and back.
Typhus fever.	4 to 12 days.	5 days.	Usually 5th day; may be on 3d or not until 7th day.	Measly spots; petechiæ; streaks; color, mulberry-red.	Few days, or may last throughout the course of the disease.	Sides of chest and abdomen; arms; back.
Varicella.	4 to 14 days.	1 to 2 days.	Within 12 to 24 hours.	In crops. Vesicles.	5 to 8 days.	Back, chest, arms.
Variola.	8 to 14 days.	3 days.	4th day.	Umbilicated pustules.	21 to 25 days.	Face, and over body.

(From *Pocket Cyclopedia of Medicine and Surgery.*)

8. In the *first stage of syphilis*, the chancre is the important lesion.

The second stage of syphilis is characterized by: Sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical. In this stage may also appear: Iritis, periostitis, and alopecia.

The *third stage* is marked by: Anemia, gumma formation, periosteal nodes, headaches, endarteritis and various other diseases.

Additional tests are: The presence of the *treponema pallidum* in a smear taken from the chancre; a positive Wassermann reaction is valuable (provided the test is made by a competent laboratory worker); the therapeutic test is also of value.

9. Gastric ulcer. *Etiology:* Injury, bacteria, hyperacidity of gastric juice, changes in the blood or blood-vessels of the stomach; it generally occurs in young people (20 to 30) and is apt to be associated with chlorosis. *Symptomatology:* Pain, localized in stomach, coming on soon after a meal, and of a sharp or cutting nature, and often relieved by vomiting; hematemesis; tenderness over the stomach; the condition is generally improved by starvation or by a milk diet; analysis of gastric contents shows an excess of free hydrochloric acid; there may be "occult" bleeding, which can be recognized by the benzidin test. Prognosis is guardedly favorable; hemorrhage and perforation are apt to be fatal complications; relapses are common; the mortality is about 10 per cent.

The condition is to be diagnosed from gastralgia, gastric cancer, hyperchlorhydria, and duodenal ulcer. *Gastralgia* resembles gastric ulcer as regards hyperacidity and the paroxysmal pains. It differs in the absence of dyspeptic symptoms between the attacks, hematemesis, and local tenderness and enlargement.

Gastric cancer may be distinguished from gastric ulcer in that it occurs at a later period in life, has a more rapid course, the cachexia and emaciation are more prominent, the pain is more constant, the growth is palpable, the vomit has a "coffee-grounds" appearance, and there is absence of hydrochloric acid and presence of lactic acid.

Hyperchlorhydria is attended only by an increase in the hydrochloric acid and pain which is relieved by albuminous food. The other symptoms common to gastric ulcer are absent. The *differentiation between gastric and duodenal ulcer* is often impossible. The latter may be suspected: (1) If the pain occurs in two to four hours after eating, and is located in the right hypochondrium; (2) if there is a hemorrhage from the bowel rather than an hematemesis; (3) jaundice is more frequent in duodenal ulcer.—(Hughes' *Practice of Medicine.*)

10. PYELITIS is inflammation of the pelvis, of the kidney, and is due to—(1) calculi; (2) tuberculous disease; (3) extension of sepsis from the bladder and urethra; (4) sometimes movable kidney; (5) the ingestion of cantharides or turpentine; (6) a pyemic embolus. The lining membrane is red and swollen, and exudes muco-pus or pus. A certain amount of hydronephrosis occurs from the blockage produced by the swelling. When pyogenic organisms are present, the kidney substance may be invaded (pyelonephritis). Perinephritic suppuration may follow from extension.

The *symptoms* are pain and tenderness over the kidney, frequency of micturition, and pus in *acid* urine, unless there is cystitis as well, when the urine is alkaline. The pyuria is intermittent when the ureter is occasionally blocked.—(From *Aids to Surgery.*)

The main *complications* are: Pyelonephritis, pyonephrosis, hydronephrosis, anuria, and perinephritic abscess.

(*To be concluded.*)

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	S. W. Welch, Montgomery	Montgomery	July 13
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix	
Arkansas	T. J. Stout, Brinkley	Little Rock	May 11
California	C. B. Pinkham, Sacramento		
Colorado	David A. Strickler, Empire Building, Denver	Denver	April 6
Connecticut*	R. L. Rowley, Hartford	Hartford	Mar. 9
Delaware		Wilmington	June 15
Dist. of Columbia	E. P. Copeland, Washington	Washington	
Florida*	W. M. Rowlett, Tampa	Jacksonville	June 14
Georgia	C. T. Nolan, Marietta	Atlanta, Augusta	June 9
Idaho*	Robt. O. Jones, Boise	Boise	April 6
Illinois	F. C. Dodds, Springfield	Chicago	Mar 1
Indiana	W. T. Gott, Crawfordsville	Indianapolis	
Iowa	G. H. Sumner, Des Moines	Iowa City	Mar. 29
Kansas	H. A. Dykes, Lebanon	Topeka	
Kentucky	J. N. McCormack, Bowling Green	Louisville	July
Louisiana	E. W. Mahler, New Orleans	New Orleans	June 10
Maine	F. W. Searle, Portland	Portland	Mar. 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 8
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston	Mar. 9
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 8
Minnesota	T. McDavitt, St. Paul	Minneapolis	April 6
Mississippi	J. D. Gilleylen, Jackson	Jackson	
Missouri	G. H. Jones, Jefferson City	Kansas City	
Montana*	S. A. Cooney, Helena	Helena	April 6
Nebraska	H. H. Antles, Lincoln	Lincoln	June
Nevada	S. L. Lee, Carson City	Carson City	May 3
New Hampshire	C. Duncan, Concord	Concord	Mar. 11
New Jersey	A. MacAlister, Trenton	Trenton	June 15
New Mexico	R. K. McClanahan, East Las Vegas	Santa Fe	
New York	G. M. Wiley, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	May 18
North Carolina	H. A. Royster, Raleigh	Raleigh	June 14
North Dakota	G. M. Williamson, Grand Forks	Grand Forks	July 6
Ohio	H. M. Platter, Columbus	Columbus	June
Oklahoma	J. M. Byrum, Shawnee	Oklahoma City	April 13
Oregon	B. E. Miller, Portland	Portland	July 6
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburgh	July
Rhode Island	B. U. Richards, Providence	Providence	April 2
South Carolina	A. E. Boozer, Columbia	Columbia	June 8
South Dakota	P. B. Jenkins, Waubay	Deadwood	July 13
Tennessee	A. B. DeLoach, Memphis	Memphis, Nashville, Knoxville	June
Texas	M. F. Bettencourt, Mart	Austin	
Utah	G. F. Harding, Salt Lake City	Salt Lake City	
Vermont	W. Scott Nay, Underhill	Burlington	
Virginia	J. W. Preston, Roanoke	Richmond	June 22
Washington*	C. N. Suttner, Spokane	Spokane	July 6
West Virginia	S. L. Jepson, Charleston	Charleston	July 13
Wisconsin	J. M. Dodd, Ashland	Milwaukee	June 29
Wyoming	J. D. Shingle, Cheyenne	Cheyenne	June
National Board	S. Rodman, 1310 Medical Arts Building, Philadelphia		

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular state.

Therapeutic Hints.

Eliminative Treatment of Influenza.—George L. Servoss of Reno, Nevada, directed all his efforts toward the prompt removal of the toxemia. He endeavored to increase skin, kidney, and bowel action, and to induce a higher vapory elimination from the air passages. He and his associates pushed stimulants of elimination to the utmost limit, and saw their patients recover promptly, none of them showing any complication whatsoever.

The treatment, which he considers the logical method of dealing with influenza, is as follows: After ordering a small dose of calomel, 1/6 grain every half hour or so, until a grain is taken, begin with

℞ Potassium iodide .....grs. 10
Liquor potass. cit. U.S.P.....oz. 4

M. Sig.: For the first 24 to 48 hours, one tablespoonful in a glass of water every hour. Thereafter, one teaspoonful in half a glass of water, every two hours on the odd hour.

After the bowels have been moved by the calomel, or the morning of the second day, the following is added to the treatment:

℞ Corrosive sublimate .....gr. 1
Syrup wild cherry.....oz. 4

M. Sig.: One teaspoonful should be given in half a glass of water every two hours on the even hour.

By pushing the first mentioned mixture to the utmost during the first 24 to 48 hours, that being based upon the sort of toxemia to be dealt with, the elimination becomes very thoroughly established. The calomel has stimulated the glandular action and this is further carried on by the second mixture. As a rule these are the only remedies which the writer employs in the average case of influenza, for he has found that, within 24 to 48 hours, there has been a marked change for the better, and at the end of four days the majority of his patients have expressed a desire to be up and about their business. If there is a high degree of toxemia it is sometimes well to raise the opsonic index through the use of some mixed infection vaccine.—*Indianapolis Medical Journal.*

Persistent Hiccough.—Relaxation of the spasm of the diaphragm and prompt relief of persistent hiccough has been found by Venegas to follow compression of the diaphragm. This is brought about by having the patient assume the supine position, flexing the legs and then the thighs to the extreme on the abdomen, thus pushing up the contents of the abdomen. This position must be maintained for ten minutes, or until relaxation of the diaphragm has taken place, and may be repeated upon return of the hiccough.—*Journal of the American Medical Association.*

THE INSTINCTS, THE EMOTIONS, AND THE ENDOCRINES IN STERILITY.

BY SAMUEL W. BANDLER, A.B., M.D.,

NEW YORK.

JUST as the newly-born inherits facial resemblance and innumerable physical and other characteristics and traits, so too is it born with instincts which, though common to all, are certainly inherited in varying degrees of intensity and combination along Mendelian lines. "Nature," the endocrine glands, the type of life, sanitary conditions, food, intercurrent diseases, etc., influence and may determine the type of physical and mental growth. Hunger, internal processes, and environment furnish the first stimuli which act on the instincts and result in emotions. Training, instruction, education, changes of a physiological and pathological nature enter into play and the result is the developing boy or girl who continues through life still acted on and affected by the same, or by altered types of internal and external influence. What is in a person is shown by his behavior. The behavior of animals, of the newly-born and of the young has informed us about instincts, and their expression in humans leads to emotions and subsequently plays an important rôle in disposition and character. We inherit our instincts, our emotions, and our endocrines.

People are well and healthy, or ill and sick. They are normal or neuropathic. They are normal or psychopathic. People may be cheerful or morose "by nature," as we call it; energetic or lazy; yielding or stubborn; full of ambition or indifferent; sweet or sour; they may have been one and have become the other. Some people are courageous, others are cowardly; some have been one or the other, and events and accidents may modify these qualities temporarily or permanently. A well person may become ill, an apparently normal person may become neuropathic or psychopathic. An individual may have been practically well always or more or less ill always. But endocrine action is the dominating factor.

Practically every adult who dies would show at autopsy an evidence somewhere of a previous tuberculous lesion. The vast majority never develop real recognized tuberculosis in any form; others develop it in a recognized form in glands, bones, joints, kidneys, lungs, etc.

If we understand the body and its ills, we seek to correct them medically or surgically.

Do we understand and study the mental and psychic make-up and mental reactions sufficiently to realize the numerous gradations between the normal mind and psyche and the gross abnormalities of either? Language shows that we should. We say "peculiar," "temperamental," "odd character," "nervous type," "hysterical," "rolling-stone," "weak character," "neurasthenic," "eccentric," without realizing sufficiently that, while we are referring to characteristics and traits, we are concerned with psychic conditions differing from the average or the normal. In fact, adjectives prove in language the purpose or intention of defining differences of any sort. Endocrine action is the dominating factor also.

The average mind recognizes the distinction between extremes; but unless trained or inherently analytical, it grasps less readily the intervening gradations. The medical mind is taught the symptoms of disease along the same lines, yet observation proves that there are gradations or variations in the intensity of practically all the body ills. The medical man knew a typical Basedow's disease when he saw it, but it has taken fifteen or more years to absorb the knowledge that there are variations in intensity down to what are now recognized as the milder forms of hyperthyroidism. The physician was taught to diagnose a well-defined case of myxedema; he now recognizes even a mild or occasional hypothyroidism. Everyone knows that from the extreme pulmonary tuberculosis, incurable and fatal, there are gradations down to the mild, incipient form which may often be recognized only by the most expert, and that too only with the aid of the most modern technical apparatus.

Everyone knows that epidemics of influenza may be not only of varying degrees of severity, but that they produce symptoms varying from the severest forms of pneumonia to simple slight indisposition. And so throughout the whole realm of medicine, our knowledge is brought to us by the study of the extreme types, because from them we receive the imprints which focus our attention on the various major and also minor details, and it is only by the recall of many seeming details that we can diagnose the incipient stages of many of the physical, mental, and psychic ills.

Therefore, to secure a knowledge concerning the endocrines and their importance, and to be able to recognize their gradations, pointing to their over- and under-activity, we must study some of the endocrine diseases in their extreme form, retaining a clear picture obtained not only through the eye but through the recognition of all the smaller manifestations. It is not sufficient to consider Basedow's disease, for instance, as simply exophthalmos, goiter, tachycardia, and tremor; one must know the innumerable changes in almost

every function of the body associated with this disease, the study of which has taught us that most valuable pathology which the dissecting table or the pathological laboratory is unable to supply. On the other hand, the pathologist, both in his gross pathology and in his microscopic work, has furnished us and will still further furnish us with a knowledge as to which of the glands, what parts of the glands, and what character of changes are the responsible seats or factors for those diseases and abnormalities and symptoms with which we have to deal.

Those most worthy and insufficiently recognized investigators who have experimented on animals have contributed a huge and most valuable quota to our knowledge of the physiological action of the endocrines and have helped us to recognize the general and the specific effects which the endocrines produce on various organs, structures, and functions of the body. The alienists and the psychiatrists have given us a knowledge of the manifestations and symptoms of mental disease and are continually finding and unraveling the mysterious and wonderful functions of brain areas, centers, and structure in their relation to mental and psychic processes.

The neurologists let us forget the Freudians by delving into the hidden and often forgotten accidents and into the resulting effects and impressions of life and experience, expose the tremendous influence, not only of the conscious but of the subconscious.

Psychologists, by their study of the primitive and inherent instincts and resulting emotions, have exposed to us the knowledge that different beings react to different stimuli according to laws often as fixed and as specific as the reaction of chemistry and the laws of physics. *But here we do not grant readily enough the association of endocrine activity with the emotions and the instincts, the most important point of all.*

The resemblance of a new-born infant to either of its parents or grandparents is due to the fact that a like endocrine action, has taken place along the phase of body-development. If a child resembles either of its parents or its grandparents in instincts, emotions, mind, and psyche, it is because a like endocrine action has taken place in the two. Twins born in the same sac have developed from the same fecundated ovum which, after its first cell division, allowed each of these two halves to develop as an independent ovum. Hence such twins are alike in sex, in appearance, in characteristics, in nature, etc. Twins which have developed from two different ova are in two separate sacs and may be, and usually are, as unlike as any two children of the same parents born at different times. When people totally unrelated resemble each other, it shows that they are the products of like endocrine action and relation. If they resemble each other in disposition, traits, and character it shows that they possess corresponding and similar endocrine activity. When people are peculiar and abnormal any who have the same deviations from the normal suggest that like or similar endocrine activity has taken place in either. When individuals have a psychosis of any definite distinct type and their symptoms are alike it suggests the same disturbance of endocrine action and interplay in two totally unrelated individuals endowed with like instincts and emotions. When individuals having the same type of psychosis react in the same way in their attitude and show more or less the same psychic elements of reaction one is justified in regarding their endocrine interplay as approximately the same. Therefore resemblances in body, form, or in features or in ability or in character or in mind or psyche are important to the physician in attracting his attention to the fact that many people who resemble each other or look alike may be and often are alike in other respects.

It is only by a bringing together of the most essential and varied points brought to our knowledge by the scientists and investigators in the fields above mentioned that a physician can obtain a sufficiently comprehensive and amalgamated knowledge of the human being as a whole.

Then comes the question of what to do and how to do it in the best possible manner. So far as the endocrines and therapy by endocrines is concerned, exact knowledge as to indications for administration and as to the value of the different gland extracts can be obtained only by their use by the human being, however much experimentation on animals may have taught us. Therefore to equip oneself adequately for endocrine therapy, these gland extracts must be tried, as they are being tried and will be tried in a continually increasing field of endeavor; each specialist of necessity studying gland physiology, pathology, and therapy in its more particular relation to his field of work. Let me say here that for years 90 per cent. of all my medication has consisted of endocrine extracts.

To initiate endocrine therapy properly in gynecology, one must attempt the study of the relation of the endocrines to the physiological functions of woman in the varying periods of her life; and must continually study the possible relation of deviations of glandular activity to many of the pathological, physical, mental, and psychic manifestations with which he has to deal. And this holds true for children as well as adults. And right here, so far as our children are concerned, is the most important field for therapy. Therefore many of the associations between glandular abnormality and pathological states are at first only suggestive as to cause and effect. But if these seeming coincidences occur sufficiently often in one's practice, the suggestive becomes the probable; and the more frequently does it repeat itself, the more nearly does it approach a fact.

Therapy aids us in the same way. If, for instance, any one gland extract or a combination of gland extracts without any other treatment cures a case of sterility, it may be a coincidence; in fact the patient might have been pregnant at the time of examination. If two or three or four other apparently normal but sterile patients, under the administration of any of the indicated gland extracts or a combination of extracts, without the aid of any other treatment, become pregnant within two to twelve weeks, it is suggestive. If a dozen sterile patients conceive under the same form of therapy, it is probable that the prescribed endocrines have caused changes of a trophic or allied nature which have resulted either in ovulation, fecundation, or

nidation where one or the other has not occurred before. If thirty cases are successfully treated in the same manner, granted that there are failures, the reason for which can be satisfactorily given in most instances but not in all, we must conclude that the physician is justified in proclaiming the fact that endocrine therapy is valuable in the treatment of sterility. And here, in order to be explicit and clear and to leave no room for possible misunderstanding, it must be understood, as all reasonable medical men would naturally understand, that the curable cases are those where normal spermatozoa are present in the partner, where there is no double pysosalpinx or salpingitis or closed tubal ends; where there are no bilateral dermoids or ovarian tumors and where the uterus is of a size sufficiently approaching the normal to lead any reasoning examiner to understand that it might conceivably serve as the nest for an embedded and growing ovum.

These are of course the grosser and easily recognized obstacles to sterility but they have their finer and not so easily demonstrated or recognized minor degrees of abnormality, such as completely cystic ovaries, or chronic inflammatory, and often gonorrheal, mucoid discharge from the cervix. Practically all cases, except such as are above mentioned, come into the realm of curable sterility.

A patient who had been married four months and whose previous menstruation varied in period between one and six months, consulted a gynecologist who performed a cervical plastic operation. A few months later she consulted another gynecologist who curetted her. When she came to me her amenorrhea had lasted nine months. Examination showed complete atresia of the cervix which I corrected at operation and a cervical stem was introduced after a thorough irrigation of the uterus. It is not easy to understand why either of the previous procedures (cervical plastic or curettage) was attempted for the correction of sterility in a patient with such a menstrual history.

Each year I see several patients in whom a curettage has been followed by either a relative or a complete amenorrhea. There is beyond doubt an intimate relation between the ovary and the endometrium. The endometrium grows thicker, the cells enlarge, the capillaries dilate for from seven to ten days before each expected menstruation, this decidua menstrualis forming an appropriate nesting structure for a fecundated ovum. As the endometrium undergoes these changes through the stimulation produced by the secretion or secretions of the ovaries aided by other glands which exert a trophic influence on the ovaries and uterus, a reaction is exerted by the secretion of the endometrium upon the ovaries and this reciprocal influence is of importance.

If the uterine lining be curetted away too thoroughly, especially in what might be called a sensitive case, the reaction on the ovaries can be appreciated, and the untoward results just called to mind speak for themselves.

The normal endometrium is not a mucous membrane to be removed without reason. The curette has its place, and well does it serve us in properly selected instances. When the endometrium is overgrown or polypoid, if uterine polypus or cervical polypus be present, if in a miscarriage all the tissues of the ovum are not cast out, if we suspect a malignant change in the endometrium, a curative or diagnostic curettage is indicated.

Certain cases of menorrhagia without appreciable change in the endometrium, certain other cases to which the name fibrosis uteri may be given, certain cases of fibroid of the uterus, respond splendidly to a curettage, especially if followed by the administration of ergot or ergotole or mammary extract, or by hpodermics of ernutin or aseptic ergot.

Is there any other danger than a resulting amenorrhea which can be mentioned or blamed on a curettage? The element which always makes me fearful is the possibility of an unrecognized inflammation.

Speaking now of women who have never borne children or who have not miscarried, a chronic discharge of greenish-yellowish, tenacious mucus from the cervix, constitutes a warning. It is an evidence not of a hypersecretion but of an inflammation against which the cervix is battling by the production of mucus. An infection may extend up through the cervix and uterus into the tubes, ovaries, and peritoneum; and the cervix may react by no mucoid discharge. On the other hand, in many cases there is an attempt on the part of nature to fight the invading bacteria and thus limit the upward spread of the infection. Why some patients respond by this mucoid means of defense and others do not, is a matter evidently dependent on many considerations belonging more or less to the question of immunity. Such cases are never dilated nor curetted by me, and for two reasons: (1) It is almost impossible to cure this cervical discharge unless the entire cervical mucous membrane is removed, for so long as the deeply ending glands are preserved the mucosa will be restored and the infection still remaining in these crypts and in the connective tissue outside of them will continue to produce the discharge. (2) But a second and more important reason is our inability to determine, in all cases, how high the infection has spread; and any curetting of the endometrium is of course contraindicated whenever an infection, latent or active, is present in the tubes and in the endometrium.

Leaving aside, however, these cases with this pronounced cervical discharge, there are only too many where an infection has spread upward, leaving in the cervix few, if any evidences. It is only when we collect on a cotton tampon placed around the cervix the secretion of the cervix and uterus for a period of twenty-four hours, and subsequently examine this discharge under the microscope, that we can with any certainty express an opinion on this all-important question. One has only to see a case of early gonorrheal infection respond favorably to conservative treatment—consisting at first mainly of douches—to note how within a few months or perhaps even a few weeks, all signs of the original vulvar, vaginal, or cervical involvement have disappeared; and it would be a bold man who could express an authoritative opinion on the areas further up without the just mentioned method of examination. It is by collecting the secretion discharged upon this cotton

tampon from the cervix and uterus over a period of twenty-four hours, and examining it under a microscope, that we remark how often a smear of pure pus cells is obtained; and if, after a period of months or years the cervical uterine discharge is negative, we still may have to deal with a latent inflammatory condition in the tubes.

It is only by comparing one's diagnoses with the findings during laparotomy that one visualizes the frequency with which salpingitis and cobweb adhesions escape the tactile sense. Therefore a dilatation and curettage may be productive of great harm if an unrecognized inflammation or a condition not correctly viewed as an inflammation, is present.

The all-important point of spermatozoa frequently receives no consideration. Often enough have I observed patients who came to me because of sterility and who had been curetted—some of them twice and even three times—when my subsequent examination of the partner showed the spermatozoa to be absent or to be present few in number, non-motile or only slightly active.

The element of hypoplasia or atrophy of the uterus and ovaries is of the greatest importance, and the greater the degree of relative amenorrhea, the less favorable as a rule is the prognosis. I am almost inclined to the belief that a menstruation every six or ten weeks, associated with a normal loss of blood, is of no worse prognostic significance than a regular menstruation of only a day or so; but it is as unsafe to state that such patients do not ovulate as it is to state that all women who menstruate normally do ovulate; for here again our experience during operations shows that many patients, in spite of regular menstruation, do not ovulate. The structure of the outer covering of the ovary may be so altered that Graafian follicles do not burst. Circulatory changes, frequently prompted by displacements, may have a like effect. The liquor folliculi bursts through the thin covering of the follicle and carries with it the ovum. But this bursting cannot be dependent simply on pressure; there must be in the liquor folliculi an enzyme or ferment which assists in this process. If because of any of these conditions the follicles do not rupture, the ovaries become filled with follicle cysts and these, together with corpus luteum rests, because of their presence, add to the difficulty of subsequent ovulation.

The cases of sterility favorable for treatment of any sort are those in which no evidence of inflammation can be found, those in which the hypoplasia is of no marked degree, and those only where spermatozoa in the male are found to be normal.

What is the treatment for these cases?

Heretofore, and even now, with many the favored plan is a dilatation with or without a curettage, or some form of cervical discission or plastic. This denotes that those who practise these methods exclusively believe the mechanical obstacle of the cervix and its canal to be the one and important factor. I do not hold to this opinion nor have I held this view for many, many years. A cervix which will admit a sound, which is not filled with overgrown endometrium, is rarely a bar to the upward movement of the microscopic spermatozoa. Besides, as I have frequently stated, the interstitial area of the tube is infinitely smaller in caliber than the cervix, and yet the ovum is passed through it into the uterus and the spermatozoa pass out through it into the tube.

My explanation as to the causation of sterility in the so-called favorable cases, fixes the blame either on the ovaries and the failure of ovulation, or on the tube and its cilia which are to move the ovum into the uterus, or on the uterine lining which is the ground in which the ovum is to nest, or on the inability of the fecundated ovum to inhibit menstruation.

If a patient pregnant eight weeks or more menstruates and casts out the ovum with its chorionic villi, we call it miscarriage, but if the fecundated microscopic ovum, without villi, is cast out when a patient is only a few days over her menstruation, we are in no position to be certain that this has been the case, yet in all probability it occurs often enough.

The most interesting phase of pregnancy is the amenorrhea. Why does menstruation fail to take place when a tiny fecundated ovum settles in the uterus, or occasionally in the tube?

Menstruation is the loss of blood poured out from the capillaries and vessels of the endometrium when no pregnancy has taken place. The endometrium, like a wet sponge, is relieved of its engorgement and returns in a few days to its normal thickness. No lining has been lost, only a few epithelial cells. Under the stimulation exerted primarily by the ovaries and possibly accentuated by a remaining ruptured follicle, the endometrium prepares itself again in the form of a decidua menstrualis for a fecundated ovum. When such a fecundated ovum enters the uterus and nests itself beneath the surface it does show a growth of cells on its outer covering; these cells do penetrate into the surrounding tissue and capillaries, but menstruation does not take place. It is too much to say that a cerain reflex stimulation has inhibited menstruation; the only available explanation is that the cells of the outer covering, entering as they do the maternal circulation—those cells which form the future chorion and placenta—by their action as a hormone, hold off the menstrual flow.

Menstruation is dependent on the normal action of the ovaries and their secretion. If the ovaries are removed, no gland extract that we can give will restore it; therefore the ovaries supply hormones and are aided by other hormones which we cannot yet supply to the body in efficient character or sufficient or proper quality. The ovaries are not essential to life. When removed, in spite of the flushes and other annoyances, duplicated in many instances at the normal climacterium, the patient's physical health is not seriously affected. These flushes are due not only to absence of ovarian secretion but to a hyperactivity of the posterior pituitary. The ovaries are of the greatest importance, however, because they normally furnish each month, in supposedly ripe form, at least one of the twenty-five or thirty thousand ova which they contain; but of all the structures of the body which have a secretory function the ovary is the weakest in that its

activity, as well as its development, is dependent on a proper trophic support by other glands; and this trophic support is quite as essential for the tubes and uterus as for the ovaries.

Pathology has taught us how profoundly the growth of the body may be held in check or stimulated or altered by the overactivity or underactivity of the pituitary gland, the thymus, the thyroid, the adrenals, etc., and it teaches the gynecologist how profoundly the genital tract is involved by disease of these same glands. An underactivity of the pituitary most profoundly affects the development of the ovaries and the uterus; but if posterior pituitary inactivity takes place after their development, it may bring about their atrophy. Affections of the thyroid gland play an important part. Aside from these changes, the genital tract may be injured by the infectious diseases of childhood or by subsequent constitutional diseases (leaving displacements and inflammations aside).

Now menstruation, initiated as it is by the ovaries and preceded as it is in normal cases by the exit of an ovum, is not a local process only. It is a constitutional involvement not experienced disagreeably by many women but associated in very many instances with what are known as premenstrual phenomena; and these premenstrual phenomena are due not only to the changes produced in the body by the cumulative action of the ovarian secretion, but to the associated altered activities of the thyroid, the adrenals, and the pituitary gland, especially the posterior lobe. The general symptoms of this recurring premenstrual period always show which of the endocrines is or are stimulated or inhibited and that the unstable member or members of the chain are disclosed. So we may say that the trophic support of the genitalia—of the uterus in particular—is dependent, not only on the ovary itself, but on the thyroid adrenals and pituitary likewise. Here we must not forget the action of the adrenal glands. If we are to initiate a glandular or endocrine therapy for sterility, we have only to point back to the rôle which pathology, if nothing else, has taught us; for tumors of the pineal gland, of the pituitary, of the adrenals, etc., have frequently enough been found to have a marked influence on growth and sex development. Acromegaly, myxedema, the dystrophias, the rarer cases of Addison's disease, etc., have their decided rôle in affecting the functions of the ovary and of the uterus, and the same holds true of the like diseases of lesser degree.

A comprehensive study of the endocrines in general is an ever increasingly huge task. One may take up this study for the sake of individual pleasure and find in it a worthy reward; but most of us have entered into the study of this all absorbing question because it seemed to furnish us not only with an explanation for many phases which seemed puzzling, but because it offered a prospect of supplying the means by which we might benefit our patients. A man may be a very good physician and yet have forgotten ninety per cent. of all the anatomy studied so laboriously and with so much drudgery in our medical schools; a man may read the entire literature of the endocrines and forget ninety per cent. and still retain the essential points and factors which particularly interest him, especially from the practical side. But he can gain a proper understanding of the problem only by observing therapeutic results.

When I was a student of medicine, Professor Allen Starr showed a case of myxedema, typical in appearance, one never to be forgotten. The patient was a school teacher who had left England because her memory had failed her; her mental faculties had changed so that her vocation could not be pursued. I remember with what glee and confidence he told us that the patient could be cured, now that we were no longer feeding with the gland itself but were giving a glycerin extract; and not long thereafter thyroid extract was used therapeutically and I have used it ever since.

I remember a clinic of Professor Delafield's, when he showed a big, broad-shouldered, powerfully built stoker complaining of palpitation of the heart. After a thorough examination, he said in words that I have never forgotten: "This is a case of exophthalmic goiter without exophthalmos and without goiter." The meaning of that diagnosis has influenced me ever since, and early in my gynecological practice I studied my cases and published a large series under the title, "Associated Nervous Conditions in Gynecology," the main purpose being to show that hyperthyroidism was a most frequent cause of these nervous conditions, and that it existed without the so-called pathognomonic signs of Basedow's disease.

Nearly twenty years ago Knauer made those interesting transplantations of ovaries in animals which proved that the ovaries exerted their trophic action on the genitalia by virtue of a secretion and not by a reflex promoted by ripening of the follicles. Since that time I have been using ovarian secretion (corpus luteum much less frequently than the whole gland), and later the secretion of the interstitial substance, both by mouth and by hypodermic; and with every year the results in an ever widening series of appropriate cases are more than gratifying.

Several years ago came the introduction of pituitrin into obstetrics, calling attention to the relation between a gland seated in the brain and an organ so distant and so special in its activities and functions as the uterus. Cushing's work deserves the highest praise, aside from his surgical accomplishments, because his reports of cases contain references to the effects of the pituitary diseases on menstruation; and the frequent references to associated thyroid anomalies and adrenal anomalies have done so much to focus our attention on what are now called pluriglandular or polyglandular involvements; that is, the fact that a severe change in one important gland influences or is associated with changes in associated glands. But an added feature is the photographs of patients in their earlier periods before a pituitary disease began to be manifested; and the photographs of the same patients at the time of operation. Could anything be more instructive than the study of the changes in facial contour, growth of the facial bones, changes in the jaw, in the teeth, in the hands, etc.? Associated therewith are the changes in metabolism and in the mental attitude, the psychic sphere.

As a result of such study one is able to note by observation of the face alone, the existence of a well-defined endocrine over- or under-activity or alteration. One may see and thus recognize the slighter changes produced by the influence of like secretory activity. No one finds any difficulty in recognizing a well-defined case of Basedow's disease or acromegaly or myxedema at sight. Between these extreme resemblances and types and the so-called minor or latent forms there are gradations of varying degree which may still be recognized by the eye. This recognition directs our attention to over- or under-activity of a gland or glands through the suggestive resemblance. Add to this the knowledge we have gained concerning the influence of the endocrines on texture of the skin, distribution of hair, dryness or moisture of the skin, character and development of the teeth, pigmentation, feeling of physical and mental languor, asthenia, the meaning of blood pressure, sugar tolerance, rate of the pulse, etc., and it is easy to recognize how hugely our diagnostic acumen has been furthered.

In diagnosis it is no longer a question of bimanual examination, of listening to the lungs, to the heart, testing the blood-pressure, examining the urine, examining the blood, etc. It is a matter of observation and also of tests to determine what the endocrines have been doing to a patient before she comes to us; and then it is for us to determine what the endocrines are doing at the time the patient consults us; and if the patient suffers from too little of a secretion necessary to her well-being, what is easier than to administer it? And if she be suffering because of an excess of any one or more secretions, what better outlook has medicine than to search for and find, if possible, the counteracting remedies?

Now, when patients come to the gynecologist, not all are to be helped by surgical means or by surgical means only. A goodly proportion of them come because of disturbances associated with menstruation. Here we have the various degrees of amenorrhea, dysmenorrhea, monorrhagia, and metrorrhagia. Not all the menorrhagias and metrorrhagias are due to polyps or fibroids of the uterus. A very large number of fibroids have no menorrhagia or metrorrhagia as a symptom. If we can hold out hope of a cure for these patients with medication, why should be dilate or do a plastic on the cervix, or curette? How is a patient, suffering from repeated miscarriage, to be benefited by the removal of the uterine lining when examination shows it to be smooth and normal?

Then we have the annoyances which precede each menstruation, of which patients complain so frequently; we have the annoyances associated with the climacterium and the menopause. Not always are climacterium and menopause coincident. Many patients believe that long periods of nervous upset, headaches, etc., must be due to some anomaly in the genital tract. This notion seems to be general among the laity, and it is only too true that gynecology of the past few decades has assisted in fostering it. Hence the mania for doing a trachelorrhaphy to correct all sorts of symptoms supposedly reflex and supposedly due to this, in my opinion, unimportant cervical condition. Slight deviations of the uterus have been corrected in thousands of cases for the same purpose.

It was because of my disbelief in this etiology and my disinclination to advise surgical procedures against my belief that my attention was directed still more definitely to aberrations of the endocrine system as scientific and logical explanations for those varying neuroses and psychoses erroneously called "hysteria" and "neurasthenia." The extent to which hyperthyroidism and hypothyroidism, for instance, are now made as diagnoses for many of the annoying symptoms formerly called, and indiscriminately so, "hysteria" and "neurasthenia," is only one of the many proofs of the correctness of this belief.

Now, coming back to the question of sterility itself; I doubt whether in the last ten years I have dilated, curetted, or done a cervical plastic (except for intractable dysmenorrhea) in five per cent. of the cases of sterility which I have viewed as curable. By curable I refer to cases where the husbands have normal spermatozoa, where tuboovarian, inflammatory, and tumor conditions were absent; and where the menstruation was normal, or if deficient, was not associated with a marked polyglandular anomaly of a type as severe as a well-developed dystrophia adiposogenitalis. Among these cases, the vast majority fell into the class of relative uterine hypoplasia. The whole plan of treatment was dominated by (1) the notion of trophic stimulation of the genital tract in those cases where the theory of substitution implied a lack of autostimulation by the patient's own endocrines; (2) the theory of inhibition in a smaller proportion of cases where menstruation was excessive; (3) the theory of stimulation and inhibition where uterine contractions with or without excessive menstruation might be presumed to expel an ovum a few days after fecundation and attempted nidation, especially if nidation occurred shortly before the menstrual period.

I found that in a certain proportion of cases the patients, during one, two, or three periods of the year, went a week or ten days over menstruation, but at other times menstruated to the day; and in this type of cases the results of endocrine treatment have been so uniformly good that I was forced to the conclusion that the menstrual wave often throws out the ovum before the nesting is completed or fixed. There is during pregnancy a recurrence of the menstrual wave at regular periods. It is painless, not recognized in the vast majority of instances, and is associated with minor degrees of molimina in others.

Some pregnant patients have periodical headaches; others have an occasional spotting of blood at intervals corresponding to the menstrual period; others bleed more noticeably. Now, others go through the experience of expelling an ovum of varying degrees of development, resulting in what we call abortion or miscarriage. We give to this latter phenomenon when repeated the title of habitual miscarriage. In other words, there is during pregnancy a constant struggle on the part of the endocrines concerned in menstruation, to produce it, and a struggle on the part of the ovum and the secretion produced by its outer covering, to

inhibit menstruation. This struggle between the two opposing forces comes to a crisis on the two hundred and eightieth day in what we call a labor. But here again not infrequently, inhibition allows the patient to go some days to weeks over her expected date; other patients are delivered a few days or weeks before the two hundred and eightieth day. Of course, in many cases this is due to the fact that ovas may be fecundated immediately after a menstruation, while other ova are fecundated shortly before the first skipped menstruation. The treatment of these latter conditions—the type of individual who goes a week or ten days over her period, occasionally, when she otherwise menstruates normally, and including all the various types with a tendency to menstruate during pregnancy—consists of trophic stimulation first and then of inhibition of the menstrual stimulus. We have used for this purpose rest in bed, the administration of opiates and sedatives; but instead of waiting and depending upon treating cases of habitual abortion only when the symptoms of expulsion of the ovum develop, or instead of relying, as we have been wont to do, on the theory that these cases must on examination evidence a positive Wassermann (which is far from the truth), we administer endocrines which act trophically on the uterus or which inhibit the menstrual stimulus, and our results improve in certainty.

It is, of course, the most desirable part of our therapy to administer the endocrines, either for the purposes of trophic stimulation or for the purposes of inhibition, on the basis of a study of the individual's endocrine make-up, seeking to find in each and every case, if possible, the special factor or factors which are at the bottom of either condition. But even if this is difficult or impossible, we do know that the ovary and its secretions, both of the interstitial and of the glandular apparatus, have a decided trophic relation to the well-being of the genitalia. We know that the thyroid gland bears a close nutritive value to the genital functions, and that the adrenal cortex likewise bears an important part of this trophic burden. As to the hypophysis, we know from the study of the physiology of the gland that its relation to the genital tract is close and that affections of the hypophysis may influence menstruation and the development of the uterus for either better or worse.

The anterior lobe, concerned as it is with the general process of body growth, includes within the field of its activities the development and function of the genitalia. The posterior lobe, as can be understood from its action in labor, is concerned with the rhythmic uterine contractions of the same; hence my conclusion that overactivity of the posterior lobe at menstruation is responsible in most cases for uterine dysmenorrhea—and therapy proves this to be true.

The thymus gland has the effect in some cases of inhibiting ovarian activity. Based on physiological study extract of the placenta should have a quieting and inhibiting effect on overactivity of the posterior pituitary. Proceeding from this basis, I have used it in a very large series of cases and have found it to be of the greatest value in those cases of dysmenorrhea and repeated miscarriage and in a large number of pelvic conditions and general states due to posterior pituitary hyperactivity. Inasmuch as the use of placental extract in threatened or repeated miscarriages has always been associated with the use of other endocrines and occasionally with the use of sedatives, the reliance that may be placed on this extract alone is not yet settled in my mind.

Since working on this theory and following this practice, I find results which, in comparison with the results obtained by other methods are not only encouraging but decidedly effective, I have not the faintest interest in proving that dilatation and curettage are never followed in previously sterile patients by subsequent pregnancy, for the record and experience of able men in gynecology proves that it is true. I simply feel that curettage and dilatation and cervical plastics have not attacked the basic factors which, in the majority of cases, in my belief and in my experience, are of greater importance. What possible error is a physician committing if he treats a case of curable sterility by endocrines before he attempts any surgical procedure? Then, if this treatment is not successful, he is the more justified in assuming that some surgical procedure is necessary. The fact that he may decide on a cervical operation, while I would be more inclined to advise the removal of cysts from the ovaries, would then furnish a basis on which we could eventually accurately measure the rôle which the cervix plays as an obstacle to impregnation. And when it comes to the question of curettage, with the subsequent restoration of a new endometrium, I hold that unless the endometrium is overgrown or polypoid, endocrine therapy restores it to a type and character favoring nidation just as well if not better and with less danger. We must understand the difference between fecundation and that continuance of nesting and growth of the ovum which we call pregnancy; and I am firmly convinced that, whatever endocrine therapy does to the ovary or tubes, in a large proportion, if not the largest, it acts trophically in aiding the ovum to nest or in retaining it after it sinks into the endometrium. In other words, union of the ovum and spermatozoon occur in an untold number of cases, but nidation or permanent nidation fails.

If this be true, it is sad to think of the innumerable unborn, still remaining in the Blue-Bird Land of Maeterlinck, whose potential mothers might have permitted them ingress into this mundane sphere.

The maternal instinct can be one of the most powerful of all instincts but is of varying degree. The same holds true of the sex instinct. But while both are associated with endocrine stimuli, both trophic and otherwise, there is a vast difference here in the intensity of the somatic effects and in the intensity of those psychic phenomena connected with either of these instincts and their associated emotions. An individual may have a strong maternal instinct and little sex urge or receptivity; and many women reconcile themselves to the sexual side of married life because thereby comes the subsequent reward of maternity. Others have the physical and psychic sex phenomena of normal or exaggerated character with little of the

maternal instinct. Children give pleasure, joy, or sorrow according to the accidents and fates of life which are theirs; and these depend much on the moulding and development of their instincts, emotions, disposition, and character. Parents take the chances associated with heredity, environment, training, education, etc., and the developing child is the product. Sterility, according to the instincts, emotions, disposition, and character of the patient may be accepted with indifference, with regret, or with a continued yearning or longing; and because of it psychic effect may spoil or destroy the desiring-to-be-mother's life.

We may on pelvic examination likewise discover conditions distinctly due to the endocrines. But the outward physical manifestations of over- or underactivity may be relatively absent, particularly if the changes in the gland relationship have been recent. We know that gland abnormality may be evidenced in one individual by predominantly physical signs, in another predominantly evidenced by altered visceral function or metabolism. In another the effect is predominantly on the mental reactions and psyche. In extreme cases there are various grades of combinations of all three.

It is most important to judge the endocrine processes of an individual at any age from childhood up, and to determine their influence on, and association with, instincts, emotions, mental and psychic reactions. All deviations from the standard in body characteristics are due to over- or underactivity of the various endocrines or to the numerous and innumerable possible variations in their interrelation. Normality and abnormality of any of the factors concerned with a child or adult are due to heredity and to inherited instincts and emotions plus the play of the endocrines.

While this point will be discussed more extensively in a subsequent article, sufficient of an outline will be given here to indicate the meaning of the above statement. Normally a definite balance should exist between the interstitial and glandular structures of the ovary; between the anterior and posterior pituitary, between the adrenal cortex and the medulla. The balance, as well as the activities of the respective structures represented in this balance differs in the two sexes, with the testis as the male gonad.

The anterior pituitary is vitally concerned with body growth and mental development. It is associated with strength, large or broad hands, the development of the jaws (we speak of a firm lower jaw), with maturity of mind, etc., and its function is more in evidence in men than in women.

Speaking in relative terms and in view of its relation to the posterior pituitary it is a male gland just as relatively speaking the thyroid is a female sex gland.

The posterior pituitiary related to the uterus and genitalia (pituitrin, for instance) plays relatively a greater rôle in its balance with the anterior lobe, in women than in men. Its action is associated with the tender emotions and with the sex instinct in women; and so far as the tender emotions are concerned plays, of course, a much more important normal rôle in women than in men. Relatively speaking, it may be called a female gland.

The adrenal structures are related to the instincts of flight and pugnacity and to the corresponding emotions of fear and anger. The adrenal cortex is concerned with the production of hair and exerts normally a greater influence in many phases in the male than in the female. Good adrenal action (cortex and medulla) is essential to courage. Poor adrenal action, especially a lack of balance between the cortex and medulla wherein the cortex plays the minor rôle, is responsible for the emotions of fear, for cowardice, for anxiety. The adrenal cortex is more of a male than a female portion of the gland. The medulla, since it is more predominant in women, is therefore partly responsible for their being more "emotional," as we call it.

The ovary is closely related to the posterior pituitary and to the adrenal medulla. This combination is responsible for the characteristics of coyness and self-display. She is not the aggressor in the sense of the hunter and fighter, she is the one who is sought. Since the anterior pituitary is less active, that maturity of mind and what we call wisdom, greatly dependent on anterior pituitary action, are less marked, and men have produced the greatest philosophers.

The male gonads are responsible for the sex urge, stimulate the adrenal cortex and the anterior pituitary more than do the ovaries in women. There are, therefore, numerous indications for the administration of the corresponding extracts in those states due to lack of sufficient adrenal cortex or anterior pituitary activity. Hence man is the fighter and the hunter, his sex instinct is much stronger, he is the aggressor and seeks the woman.

There is in woman no such mechanism producing the consciousness of sex urge as man has in the testis, vas deferens, and seminal vesicles. The combination of testis and adrenal cortex makes man more brutal, more criminal and more coarse. It is the normal action of the anterior pituitary which is concerned with that cerebral trophic stimulation and with that maturity of mind and with that judgment which in most men act as restraining factors to the coarser instincts. A normal associated action of the posterior pituitary has a like moderating action, and if it be excessive in men, even though it does not overbalance the action of the anterior pituitary, such men are more or less emotional, have tender feelings, are fond of children, etc.

The thyroid is the great activator. According to its action it stimulates, understimulates or overstimulates any of the functions, instincts, or emotions of the human being. It is much less stable and much more frequently overactive in women than in men. It is the great fixer of impressions for all things in the sphere of memory especially for all things not associated with those instincts and emotions which are specifically associated with the activity of other endocrines.

When events, occurrences, etc., which act on the instincts and arouse emotions do prompt a response, there is an endocrine activity which varies in degree and in the gland involved according to the instinct and emotion affected, and this particular endocrine, or endocrines, act as fixers in association with the thyroid.

A distinct neuroendocrine path is created by every stimulus through any of the senses. Any event, process, or stimulus which has brought into

activity any endocrine secretion specifically associated with the emotion aroused, may be recalled, or the recall is made more easy by a subsequent activity of that endocrine. This constitutes what might be called reverse peristalsis, and plays the all-important part in dreams, and in determining the character of the dreams.

If a little child three years old, before retiring is roused into a tempest of anger by anyone and a few hours later that little child in its dream shows the emotion of anger and cries out the name of the person responsible for the emotion, how are we to explain this phenomenon? What more logical and correct explanation can we give than that the adrenal outpouring associated with the emotion of anger has continued its activity during sleep and has reawakened the subconscious sphere and in part the upper sphere, to a reproduction of the original picture? Considerations like these should make us regard the bedtime hour of children as the hour of their greatest happiness. If certain fairy tales and stories that unwittingly rouse fear were banished entirely from the lives of children the adult would have fewer phobias, fears, and anxieties.

The correction of sterility does not as is the province of medicine, simply benefit a mental state, correct an ill, or save life; it helps to create life.

I have never told a patient that the fault is her husband's, however often this may be the case. Sterility is so frequently productive of depression and psychic disturbances, the causes of domestic infelicity are numerous enough, why add this new brand to a smouldering or even brighter flame? I tell the patient to take the medication for several weeks only, that it may produce a favorable effect only after months or years; or that causes which we cannot discern and correct may right themselves even after a long interval of time. The disadvantage of this advice is that it makes the patient think the method is useless (which is a burden physicians have to bear continually in their practice). Another disadvantage is that it often throws the patient into hands favorable to dilatation, to curettage, discission, or cervical plastic, regardless of or in ignorance of the absence of spermatozoa. Perhaps this is not always so unfortunate a result, for the patient then feels that she has exhausted every known means for the treatment of her sterility. Time, plus resignation and philosophy, may then remove the too absorbing mental concentration.

In "The Medical Clinics of North America," ii, 4, I tabulated a series of fifty cases of sterility showing the number due to tuboovarian conditions, the number due to absent or inactive spermatozoa, the cases which did not become pregnant, though spermatozoa were normal, and the cases which became pregnant—five after operation on the tubes or ovaries and twelve after endocrine therapy.

The purpose of this tabulation was an attempt to show the relative importance of tuboovarian conditions, absent or faulty spermatozoa, and marked alterations in menstruation in their relation to sterility, and by reporting the proportion of cases cured by endocrines, to arrive at various conclusions concerning the entire question of sterility.

In a subsequent paper will be published a report of cases in which endocrine therapy was the only treatment given, a second series of fifty cases dealing only with the type which evidences no tangible pathology; the paper will likewise record not only the successes but the failures, with the suggestive reasons for the latter.

In conclusion, I should like to warn against the tendency to prescribe definitely combined formulæ in tablet or other form, when such combinations are recommended as the correct therapy for certain and many of the conditions now known to be due to endocrine abnormality. The physician then loses touch with the theory and explanation of the innumerable pluriglandular states and the study and analysis of all the factors entering into diagnosis are neglected. In the past this has been a serious hindrance to accurate diagnosis and to the proper interpretation of the therapeutic value of the drugs entering into many of the combinations. The physician ought not to further the habit among the laity of taking drugs of any sort except on medical advice, for if he does anything to foster this habit he will be more and more looked upon as a man needed only for advice and help in those states and conditions which the public feel they cannot correctly diagnose and treat alone.

134 West Eighty-seventh Street.

THE PANDEMIC OF INFLUENZA AS IT AFFECTED CANTON, CHINA.

By WILLIAM W. CADBURY, M.D.

CANTON, CHINA.

The literature on the recent epidemic of influenza as it appeared in Europe and America has now reached a volume of considerable proportions. Little or nothing has appeared, however, on the disease in China and other parts of Asia. The present paper is an attempt to describe the epidemic in Canton. For other parts of China we have been unable to secure much reliable information.

The city of Canton extends about five miles along the banks of the Pearl River, on its north and south sides. The institutions named below are situated on or near its banks. On the south bank of the river we find the Canton Christian College at the extreme east and the Pui Ying School and the True Light Seminary at the extreme west. The Hospital for the Insane and the Blind Schools are near together on the middle south bank. On the north side of the river the Kung Yee Hospital is located at the extreme east, the Congregational School for Girls at the extreme west, and the Canton Hospital and Post Office are near together about midway between these two.

The first appearance of the disease was in the middle of June, 1918, when it appeared first at the Pui Ying School, then among the employees of the Post Office and the staff of the Canton Hospital, the Canton Christian College, and the Kung Yee Hospital. The other schools entirely escaped. Eleven days were occupied for the disease to spread from one part of the city to the others.

The second return of the disease was in October, when it was first noted in patients at the Hospital for the Insane, then at the Schools for the Blind,

close by, the Canton Hospital, the Canton Christian College, the Pui Ying Schools, the Post Office employees, and finally at the True Light Seminary. About three weeks were required from the outbreak at the Hospital for the Insane to the appearance at the True Light Seminary, but the other institutions were all attacked within six days of each other.

It will be noted that the spread of the disease in Canton was relatively rather slow as compared with its spread throughout the camps and large cities of America over far vaster areas. This may be explained by the slighter virulence of the epidemic and the slower methods of travel in and about Canton. It is remarkable to note that the period of the epidemic in Canton coincided almost exactly with its appearance in the United States and many other parts of the world.

A definite appearance, for the third time, of the disease in epidemic form occurred in the months of December and January. At this time only the Canton Christian College and the Pui Ying School were affected. Almost no cases having occurred in the other institutions. It will be noted that the Congregational School for Girls in the western part of the city escaped the disease entirely.

From the latter part of January, 1919, to the present writing—August, 1919—there has been no marked return of the disease, although there have been a number of sporadic cases, especially during the past June and July.

When we come to consider the disease itself it seems impossible to give a complete review of the extensive literature that has appeared. We should like to record especially our indebtedness to the articles of Soper: "The Pandemic in the Army Camps,"[1] and of MacNeal: "The Influenza Epidemic of 1918 in the American Expeditionary Forces in France and England."[2]

Etiology.—Nationality: The disease in Canton rarely attacked Europeans or Americans, and when it did so, only in mild form. One American family, consisting of a man, wife and four little children, were all slightly affected early in January. A few days later their Chinese cook, boy, and washerwoman came down with a very much more serious form of the disease. No deaths among foreigners have come to my knowledge in Canton. Reports from Shanghai during February and March indicate that a number of Europeans were seriously affected by the disease there, with several deaths.

Sex:

Table I.—Sex Incidence.

		June.	Oct.-Nov.	Dec.-Jan.	Total.
Canton Hospital	No. of male cases	28	15	....	43
	No. of female cases	13	12	....	25
Canton Christian College	No. of male cases	25	67	38	130
	No. of female cases	....	2	29	31

At the Christian College the great majority of the students are boys. There has seemed to be a tendency for males to succumb to the disease more readily than females. Dr. Niles, of the Schools for Blind Boys and Girls reports that all of the 13 boys were taken sick and were much sicker than the girls, of whom only 87 out of a total of 116 were affected.

Age: The age of those who died in America was generally from twenty to forty; in Europe the greatest incidence is said to have been between five and forty-five years. Over forty-five it was much less common. In the epidemic of 1890, on the other hand, the incidence over forty-five was much greater relatively. The ages of those affected in Canton may be seen by reference to the table.

Table II.—Age Incidence in Canton.

	Date.	Years 1-5	Years 6-10	Years 11-20	Years 21-30	Years 31-40	Years 41-50	Years 51-60	Total Cases.
Canton Hospital	June	..	..	5	5	3	..	1	14
	Oct.-Nov.	2	6	7	4	3	3	..	25
Canton Christian College.	June	..	..	4	7	2	1	..	14
	Oct.-Nov.	..	7	44	14	..	..	..	65
	Dec.-Jan.	10	5	40	6	4	1	..	66
Totals	.....	12	18	100	36	12	5	1	184

The above table shows a very marked preponderance of cases among children of 11 to 20. In the epidemic of October and November the great majority of cases were in children between 10 and 15, there being 40 of these ages out of a total sick of 65. The older boys were relatively slightly affected.

Occupation: Every class and every occupation was affected by the disease. At the Christian College naturally the great majority of cases were in male students. The classes are graded much as in the United States, beginning with boys of 8 to 10 in the primary second grade. In the June epidemic school closed and the students returned to their homes on June 20, so that only five students were taken sick, with seven teachers and thirteen workmen. The students were enrolled about as follows:

Primary school, 150; middle or high school, 261; college, 120; total school children, 531, of whom less than 30 were girls. Teachers and families, 180; household servants, 62; coolies and other workmen enough to make a total population of almost 1,000 persons. The primary school children are housed in four brick cottages in one part of the campus and the other students in four brick dormitories in another part of the campus. The girls are located in a building at some distance from the other two groups of buildings. Faculty and workmen are pretty well scattered over the campus. Table III shows how heavily certain sections of the community were affected.

Table III.—Distribution of Cases at the Canton Christian College.

	Primary School.	Middle School.	College.	Faculty and Families.	Servants and Workmen About:
Total number of persons enrolled	150	261	120	180	289
October epidemic	40	12	11	4	2
December epidemic	16	26	.....	17	8

Thus in the October epidemic the disease affected chiefly the little boys in the primary school and during the winter the middle school was more involved. In October none of the older girls were taken sick, but in December 15 out of 29 in the girls' dormitory were affected. The relatively small number of workmen, members of the faculty, and college students who were taken sick is quite striking.

Microorganisms: No reference need be made to the extensive literature on the bacteriological findings during the recent epidemic of influenza. Suffice it to say that the consensus of opinion seems to be that the Pfeiffer bacillus, together with the pneumococci and streptococci are secondary invaders. No bacteriological data are available for Canton. The late Dr. Harold MacFarlane, bacteriologist for Hongkong, informed me that he had isolated the influenza bacillus from a number of cases dying of pneumonia in Hongkong during June. Dr. Arthur M. Stanley, Health officer for Shanghai, writes as follows under date of Feb. 11, 1919: "Pfeiffer's influenza bacillus was usually absent; *Micrococcus catarrhalis* usually found."

Symptomatology.—Soper[1] in his valuable article describes the appearance of the disease as an explosion. He says: "The maximum effect of the epidemic has been felt within ten days after the onset. The duration has been less than three weeks. Within about a week after the outbreak of the influenza there occurs an ominous prevalence of pneumonia. The pneumonia does not exist as a separate epidemic, but always as a follower of influenza. How the two diseases are related is not positively known. It is clear that the influenza paves the way for the pneumonia if it does not actually produce it. The time of greatest incidence is usually about a week after the greatest incidence of influenza."

The disease appeared in two forms in Canton, one in June and the other in the fall and winter. These two forms correspond in general with two distinct types reported from Europe and other parts of the world.

The following observations were made in Canton during the June epidemic. The disease was ushered in with or without a chill, usually without. The temperature rapidly rose to 39° to 40° C. (102.2° to 104° F.), with no marked prodromal symptoms. The maximum temperature recorded at the Canton Hospital was 40.2° C. (104.5° F.). Headache, pains in the back and limbs were severe in all cases. Vomiting and anorexia were often present. Bronchial symptoms were generally entirely absent or very slight. The sicker cases had fever from 5 to 7 days. In 14 cases at the Canton Hospital 9 had fever from 5 to 7 days. Two had fever from 3 to 4 days, and 3 from 8 to 12 days. The cases as seen at the Christian College were milder, the elevation of temperature lasting but 2 to 3 days. There was nothing very characteristic about the temperature curve. Except for the absence of an eruption the disease greatly resembled dengue fever.

The autumn and winter epidemic showed quite a different symptomatology, with bronchial symptoms verging on pneumonia, or actually developing into a true bronchopneumonia. The symptoms corresponded quite closely with those reported from abroad, where the disease appeared in a mild form. It has been suggested that the marked absence of bronchial symptoms in the June epidemic and their general appearance in the fall and winter might be explained by the different meteorological conditions. In order to test this theory we record below the comparative figures for the months of June and July, when the first epidemic occurred, and for September, October, November, December, and January, when the second and third epidemics appeared with their attendant bronchial complications. For the meteorological data herewith presented I desire to express my obligation to A. Hotson, Esq., Harbor Master for the Chinese Maritime Customs in Canton.

Table VI.—Average Daily Rainfall in Inches.

June.	July.	September.	October.	November.	December.	January.
0.55	0.33	0.21	.....	0.16	0.02	0 016

By comparing the data exhibited in Tables IV, V, and VI, several facts are evident.

1. The maximum, minimum, and mean temperatures in October, when the second epidemic with marked bronchial symptoms first made its appearance, were but slightly lower than were these temperatures during June.

2. The relative humidity for June and July was very much higher than that recorded for September, October, November, December, and January.

3. The daily rainfall averaged highest in June and July, while no rain fell in October and but little fell in September, November, December, and January.

It is evident, therefore, that if the meteorological conditions had anything to do with modifying the symptoms of the disease at its different appearances, the bronchial complications should have been most apparent during the spring and not during the dry and only slightly cooler fall and winter months. It would seem safe to say therefore that meteorological phenomena can be excluded as bearing upon the nature and course of the disease.

At the Canton Christian College, during the October-November epidemic every person affected by the disease was seen by the author. More than 91 persons out of a total population of about 1,000, or about 9 per cent., were affected. In 69 of these a careful history and temperature record was made. The patients were seen on the first day of the fever and kept in bed until thoroughly convalescent. The first case was taken sick October 15 and the last one on November 5, an interval of 21 days. As in June, there were practically no prodromes. A chill occurred in 14, or 20 per cent. (in 6 of these the chill was very slight); there was no chill in 55, or 80 per cent., of the cases. Cough and other signs of bronchial catarrh were present in 65, or 95 per cent., and absent in 5 per cent. The maximum temperature was as follows: 40.7° C. in 1 case; 40.5° in 1 case; 40.4° in 3 cases; 40° C. and over in alto-

gether 21 of the 69 cases. At the Blind Schools one boy was reported to have had a temperature of 41.7° C. (107° F.) within 24 hours of the onset, followed by death.

Headache and general pains were not very pronounced, and delirium was rarely noted. The cough was persistent, lasting often for a week or more after the temperature had returned to normal. There was no case of pneumonia at the college. The patients were sick from 1 to 12 days with fever. Of 66 cases of whom a record of the fever was kept throughout its course we note that 16, or 24 per cent., had fever from 1 to 3 days; 27, or 41 per cent., had fever 4 to 5 days; 18, or 27 per cent., had fever 6 to 8 days, and 5, or 8 per cent., had fever 9 to 12 days.

At the Canton Hospital the first case admitted was likewise taken sick October 15, and with one exception all were taken sick before November 11. One case with pneumonia had a temperature of 41.2° C. Cough was severe in all but three of the 27 cases; 11, or 41 per cent., developed pneumonia. Of the non-pneumonia cases at the Canton Hospital 2 had fever from 4 to 5 days, 7 from 6 to 7 days, and 6 from 10 to 13 days. One child who had convulsions died after thirty days. The patients with pneumonia who recovered had fever from 10 to 24 days. Those who died were sick from 7 to 14 days. In one case a peripheral neuritis developed. My colleague, Dr. J. W. Wright, reported several cases admitted to the surgical service of the Canton Hospital at the time the epidemic was at its height, with retention of urine. These regained their normal function after catheterization once or twice. Gastric symptoms were marked in two, delirium and convulsions were also noted in a few. Dr. Niles of the Blind Schools has called attention to the fact that hemorrhages were a striking feature among the sick at these institutions. In five the blood came from the nose or bronchi, in one from the vagina, and in two from the lungs.

Following the subsidence of the October epidemic there were occasional sporadic cases noted at the college. Some of these were diagnosed benign tertian malaria, others doubtless were influenza. On Christmas Day, however, the family of a member of the Chinese staff were taken sick, and from December 25 to January 9, 16 days, there were 64 cases of illness. The symptoms were identical with those of the October attack. The highest temperature reached was 40.6° C. (105.1° F.). Out of 52 cases the temperature rose to 40° C. (104° F.) or over in 15. As to the duration of the fever at the Christian College during this December-January epidemic, in 18, or 36 per cent., it lasted from 1 to 3 days; in 19, or 38 per cent., it lasted from 4 to 5 days; in 11, or 22 per cent., it lasted 6 to 8 days, and in 2, or 4 per cent., it lasted from 11 to 16 days. Thus as in the October epidemic the disease usually lasted from 4 to 5 days. There was one case of pneumonia, a servant, who had been in poor health for several weeks. She died with typical signs of septic bronchopneumonia after having been moved to the Canton Hospital.

Pneumonia.—Dr. McKenny of Hongkong, in a personal note, states that "for practical purposes there was no pneumonia in the early epidemic and about 20 per cent. showed pneumonic symptoms in the second outbreak. In the Tung Wa Hospital there were probably 25 to 30 per cent. of pneumonias."

In Canton the writer knew of no cases of pneumonia during the June epidemic. In October-November there was no case at the college, but at the Canton Hospital there were eleven cases and in January one case. Pneumonia was especially prevalent among the children at the Blind Schools. The patients generally had shown symptoms of influenza earlier and the pneumonia occurred as a relapse, sometimes after the patient had been up and about for a day or two. This complication was often ushered in by a chill and a rise in temperature. One striking characteristic was expectoration of pure blood suggesting the hemoptysis of pulmonary tuberculosis. The temperature fell by lysis rather than by crisis. The physical signs were those of diffuse bronchopneumonia.

Leucocytes.—According to reports from abroad there is a leucopenia, with a slight leucocytosis toward the end of the fever. Lennox[3] in Peking records counts of 2,000 to 18,000, averaging 6,000. Prior to the tenth day counts averaged normal or below. On the twelfth and thirteenth days a slight leucocytosis was observed.

In June the leucocytes were counted by us in two cases. In one they numbered 6,000 and in the other 5,400, a differential count showed 80 per cent. of polymorphonuclears, 14 per cent. of small mononuclears, 4 per cent. of large, and 2 per cent. of transitionals. In October two counts were made in cases without signs of pneumonia and these were 7,600 and 1,280. In the pneumonia patients six cases averaged 7,300, the maximum count being 11,800 and the minimum 4,200.

Betchov,[4] in Switzerland, speaks of a characteristic fever curve with two high peaks at a two or three-day interval, and the exacerbation of symptoms which parallel these double peaks. He explains this by assuming a multiple virus, twofold at least. The first is filtrable and ultramicroscopic, and traverses countries with remarkable rapidity. The second peak is the work of ordinary germs, especially the pneumococcus. Tucker[5], in Boston, says that in seventy-two hours many cases have a normal temperature, but there is a recrudescence of fever twenty-four hours later At the Canton Christian College many of the students had had attacks of tertian malaria previously and these exacerbations of fever were at first considered to be malarial. However, no quinine was given in some of these cases and no further rises in temperature were noted. The two peaks of high temperature varied from twenty-four hours to four days apart.

Recurrences.—Foley[6] speaks of two cases who were attacked in October and were again affected in December, one of them dying of bronchopneumonia. In general, however, one attack seems to convey immunity to subsequent ones. It is because of this apparent immunization conferred by the June epidemic that we have felt justified in calling it true influenza.

Thus at the Canton Hospital seventeen of the Chinese male internes and nursing staff were affected in June and three escaped, two of these three were attacked in October, but none of the seventeen. In June ten of the female staff were sick

and two escaped. None were affected in October or December.

Similar conditions prevailed at the Kung Yee Hospital. At the Christian College Mr. S. of the Chinese staff was sick in June. His wife and three children fell ill in December, but he himself escaped. One student who had a typical attack from October 29 to November 4, had a slight attack of fever November 29 to 30, which might have been a recurrence. We have seen no instances in Canton, however, of one person having two typical attacks of influenza between June, 1918, and April, 1919.

Family Infection.—A striking feature was the way in which one family would be completely prostrated by the disease, while other families living next door or very near by would entirely escape. Thus in October there were the following instances at the college: Mr. and Mrs. C., infant child, and three servants; Mr. and Mrs. H. and five children; Mr. and Mrs. T. and infant, and Mr. and Mrs. W. and family. All of these were members of the Chinese staff and they with their entire families were affected. In December Mr. and Mrs. H., three children and three servants, were all sick at the same time. Also Mrs. B. and two children. These were members of the foreign staff. Mrs. H. of the Chinese staff and her seven children were all prostrated at one time, while other families in the place were only slightly if at all affected.

Deaths.—In September, October, and November it is estimated that there were more than 400,000 deaths from the disease in America. Among the troops from September 20 to November 1 there were reported 725 deaths from influenza and 18,704 from pneumonia[1]. In the cities of America the death rate per thousand ranged from 1.8 in Milwaukee to 7.4 in Philadelphia for a period of ten weeks.[7] At the Christian College only one death occurred between June and January, or a rate of one per thousand for the entire time of the three epidemics.

Elsewhere in Canton the disease also seems to have been much less malignant than in the United States, although there were rumors of entire families being wiped out and of 500 deaths in one block of a city street. At the Canton Hospital there were no deaths in June and only four in twenty-seven cases in October.

Rumors indicate that the disease was much more fatal in certain outlying districts, but the reports from Hongkong and Shang-hai agree with our own observations that the death rate was extremely low in China. That tropical countries did suffer severely from the disease is shown by reports from the Philippines and from India, where more than six million are said to have perished. As Christian[8] declares, it is a misnomer to speak of some deaths as due to influenza and others due to pneumonia, since death in this disease is practically always the result of pneumonia.

Treatment.—A careful review of recent literature indicated that vaccination against influenza if of very doubtful if any value. The only really effective therapeutic measure in the more serious cases of pneumonia seems to be the intravenous injection of the blood serum of convalescent influenza patients. This seems to have had really curative value. It is our belief that putting the patient to bed at once, with careful nursing until he is thoroughly convalescent, is the surest means of warding off pneumonia and death. Although quinine was given in a number of cases, we would not venture to ascribe any specific value to its use.

Summary.—1. Three definite epidemics of influenza appeared in Canton during the spring, fall, and winter of 1918.

2. The epidemics in Canton coincided in time with the appearances of the disease in Europe and America.

3. In Canton foreigners were but slightly affected.

4. The male sex seemed to suffer most severely.

5. At the Christian College the majority of the cases occurred in boys between 11 and 20 years of age; the older students, faculty, and servants were affected in relatively much smaller numbers.

6. The disease appeared in Canton in two distinct forms, one in the spring and the other in the fall and winter. The spring epidemics was mild, fever lasting but to four days. The second and third epidemics were more severe, cases of pneumonia developed and the fever usually lasted from four to five days.

7. Leucopenia was generally present.

8. The fever surve often presented two high peaks from twenty-four hours to four days apart.

9. One attack of the disease appeared to confer immunity against subsequent attacks.

10. The disease tended to affect all the members of a single household.

11. The mortality in Canton was relatively very low.

DREAMS OF THE FEEBLE-MINDED.

By WILLIAM S. WALSH, M.D.,

PROVIDENCE, RHODE ISLAND.

By the feeble-minded are meant those persons who from birth or an early age suffer a permanent, partial, or complete arrest of cerebral development, by reason of which they are unable to compete with any marked success with their normal fellows, or manage themselves or their affairs with ordinary prudence. Depending upon the amount of their intelligence, as gauged by various methods of mental measurement, the feeble-minded are, chiefly for purposes of classification, divided into three main groups or classes, namely, idiots, imbeciles, and morons. Idiots have a mentality which is roughly comparable to that of a normal child between the sixth

month and the second chronological year inclusive. Imbeciles have an intelligence comparable to that of a normal child between the third and the seventh chronological year inclusive. Morons' intelligence averages that of a normal child between the eighth and the twelfth chronological year inclusive. Each of these classes is further divided into three groups.

In other words, the feeble-minded are persons doomed to perpetual childhood of mind, no matter what the size of their bodies or their chronological ages. The higher grades are often unmarked by any crass physical defects, and frequently possess a superficial brilliance apt to deceive all but a trained observer. Not a few of them become criminals, vagrants, ne'er-do-wells, and social derelicts of one sort or another; moreover, their true mental status is often unrecognized, for which reason, among others, the feeble-minded offer one of our most pressing social problems. However, we should not be led astray by the published reports relative to feeble-mindedness and social evils of all varieties. Judging by the statistics prepared by some enthusiastic, possibly over-zealous workers, one would think that the feeble-minded were, as a class, not only potential but actual enemies of normals. A person can be deficient, so far as intelligence tests are concerned, and yet be well endowed with character traits of a desirable kind; on the other hand, a person may pass the tests very creditably and yet be noticeably deficient in moral sense. In spite of the common opinion, many of the feeble-minded are good characters, and go wrong only exceptionally; they may not startle the world by their brilliance, but they are indispensable for the brilliance of others, since it is they who perform the work which, to normals, is menial. One who is familiar with Dickens will find many feeble-minded characters depicted very sympathetically; as in the persons of Barnaby Rudge, Mr. Dick, Miss Podsnap, Maggie of Little Dorrit fame, David Copperfield's sweetheart.* The real problem connected with mental deficiency is the discovery of those who have a moral deficiency in addition to a general intellectual deficiency; these are practically prone to be social offenders, and require segregation as a rule. The others can, with a little supervision and sympathetic guidance, prove capable of living honorably and usefully in the outside world.

In the early part of 1919, the writer, while connected with the Maine School for Feeble-Minded, spent several months in studying the dream life of the inmates. Since it is difficult to arrive at any exact idea as to what idiots and low grade imbeciles dream about, the study was centered on the higher grade defectives. However, judging by the facial expressions and other actions of the lower grade defectives during sleep, an observer would conclude that dreams of satisfying the pleasurable instincts and of escaping danger were the usual ones of this group.

Inasmuch as the feeble-minded as a class relish attention, the possibility of fabricated dreams being recorded was rendered slight by collecting the dreams in an indirect manner. Many of the children—all inmates are called children, irrespective of their chronological ages—were in the habit of relating their dreams on awaking to fellow inmates or to their matrons. The latter were instructed to "listen in"; also to encourage the children, without exciting curiosity, to relate their dreams. The night watches were asked to note sleep disorders, and to pay particular attention to talking in sleep; when the latter occurred, the name of the talker, the hour, and what was said were recorded as accurately as possible. Since dreams accompanied by actual movement are not remembered as a rule, valuable insight into the dream life was obtained in this manner. The writer also made it a point to question the children.

The present study is based on the dreams of at least 100 defectives, the ages of the latter ranging from six to forty. In this place the writer expresses his thanks to the various employees of the Maine School, without whose cooperation the study would have been incomplete.

As is well known, Freud and his disciples believe that behind every dream a hidden wish element can be found, which may not be apparent in the dream as remembered (the manifest content), but which can be discovered by analyzing the dream for the thoughts on which the dream is built (the latent content). In my studies no serious efforts were made to analyze the dreams. For one good reason, the feeble-minded, because of their mentality, are not good subjects for dream analysis.

Of the dreams collected, those in which a wish was plainly fulfilled were very frequent. Such dreams were of being at home, of working in a good family, of having pretty clothes, good things to eat, etc. The fact that the dreamers were in institutions doubtless had an influence on the dreams; thus, dreams of being at home were the most common of the wish dreams. The wishes were, for the most part, very simple. This is quite true of their reveries also. Few of the feeble-minded have lofty ambitions. The majority desire to be out in the world doing some simple work. The boys think that working on a farm, driving horses, bell hopping, etc., are very desirable occupations; the girls almost invariably prefer housework. Few express a desire to have homes of their own, to travel, to study, to become skilled workers, to be famous. To be free, to enjoy life in simple ways, with no thought of the morrow or fear of the future, are their natural aspirations. Since these thoughts prevail by day, they tend to figure in the night thoughts, since it is on day-dreams that many night-dreams are built. The simpleness of the thought processes, the tendency to think directly, the paucity of mental associations, the poor imagination, will explain the childish nature of the dream thoughts, and will account for the ease with which the dreams are generally interpreted.

The following are some examples of simple wish dreams. The dreamers are aged thirty and more chronologically:

I dreamed I got a lot of boxes and they were filled with beautiful dresses, all lace and ribbons, and I was going to parties and having a fine time.

I dreamed I was at my brother's and out in the

*Cited by Ireland in Mental Affections of Children, 1900.

barn getting eggs, and found a lot of them, and went in and ate a lot of them, and woke.

I dreamed I went away from here and I was near a big body of water, and someone came and asked me if I wanted to get into his boat and go fishing. And I went, and we kept dropping our lines in, and just as fast as we baited the hooks we pulled up nice big fishes. And when we went home it was evening, and oh! what a nice time I did have. I love to fish. I was frying the fish when Mrs. —— called the ward.

The following is a wish dream of a more complex type. The dreamer is an epileptic, aged 16 chronologically, 10 mentally:

I dreamed that E. C. and R. D. got into a fight in the sewing room, and E. C. struck R. D. in the back. I came up and reported it to you (the matron).

This dream is the fulfillment of a wish for revenge. On the day preceding the dream the dreamer was asked by E. C. to return certain articles she had filched from the sewing room. She resented this at the time; and R. D., another inmate, laughed at her. By fighting the inmates render themselves liable to correction, which consists in sending the offenders to bed for a short time. Thus, the wish is to have the girls who offended her sent to bed, punished.

The following are a series of dreams typical of the dreamer. She is aged 35 chronologically, 12 mentally, and is the mother of several illegitimates.

I dreamed I was away from here by permission to wait on a lady who was ready for confinement. I just got there and the baby was born. And the doctor was showing me how to fix the cord. And he said: "Well, if you can't fix it I will come in the morning and fix it for you." And I was working and working to fix it. And when the doctor came he said it was all right. I washed and dressed it and laid it beside the mother. He then said: "I think you'd make a good nurse, and I have a dandy hospital, and you can come and try and I'll pay you good wages and your washing done." He said: "I am single and have never found anyone to have me, and I think you would make a good wife. We'll go over to the hospital." And we got there. It was a grand building and furnished beautifully. I said: "I feel kind of shaky coming here to work." And he said: "Why, I'll be right here." And I thought in a little while that he and I were married and I had a handsome dress and we went on a long journey.

I dreamed I was hired in a beautiful home and a new baby was born. And I was cuddling and holding it up. And she came out of the ether and said: "Oh, let me take that baby!" But I kept holding it, for she was not herself enough to trust it to her. It was our own doctor at —— who was with her and he seemed surprised to see me there. The house was furnished beautifully.

I was at a farmhouse and it was evening; and we went after the sheep and came to another farmhouse. And away down in the valley were a lot of ducks swimming. And then I went back and had a fine supper, and I went to sleep. And when I woke up I was in a nice room all my own and I said: "Now I'm out, and I won't ever go back to that feeble-minded school again." It might be mentioned that when the dreamer really awakened she cried hard, and threw things around, because her good fortune was all a dream.

Dreams dealing with the events of the previous day were numerous. As is well known, most dreams, if not all, are instigated by some incident, usually insignificant, of the previous twenty-four or forty-eight hours, though in the dream as remembered the instigator may not be apparent. Most of the dreams accompanied by talking in sleep dealt with the day's activities. The girls held quarrels with other girls, talked to various employees with whom they were associated during the day, indicated that they imagined they were at work in the dining room, laundry, etc. The boys quarrelled also, talked to their horses or oxen, etc. During the baseball season some wards were very noisy because of baseball dreams. Quarrels, especially near bedtime, often caused dreams accompanied by warm language, especially in excitable inmates.

As a rule the dreams were of a happy nature. For instance, one gray-haired imbecile dreams frequently that two former inmates who died of influenza are flying around in the sky; they have wings, but no clothes; they look like angels. Occasionally, the younger inmates dream of being chased by tramps, by a dog, bear, of being in a burning house. Generally it is not difficult to trace the dreams to previous experiences. As a class the feeble-minded are not imaginative, and thus vivid dreams are uncommon. In the case of an epileptic moron, aged 27 chronologically, a dream of caterpillars, which were crawling all over her, occurred the night before an attack of status. Between seizures, while unconscious, she talked of caterpillars, and at such times betrayed great fear. This interesting case the writer intends to publish at a later date. The following are a few examples of terrifying dreams.

I dreamed that H. J. had a convulsion and fell in a large tub of soft soap. When they got her out she was bleeding all over, and the girls were laying her across the top of the chairs asleep.

I dreamt that I went away from here to another place and I thought they asked me how I liked the place where I was. I told them I didn't like it at all. And they asked me if I wanted to go out for a walk. I said "Yes," and went out. I thought I went through the woods. While in the woods I ran into this bear. I thought he was ugly. He jumped up and leaped at me. I ran three or four steps, and he grabbed hold of my dress. I screamed. I thought I got away from him, and picked up a stone and threw it at him. I thought he went away. The night watch came in and asked me what was the matter.

I dreamed that I was here and got word that mamma was sick. And I got home and I said: "Oh, dear! Mamma is dead and I can never speak to her." I could see her just as plain as I ever did see her. And the lights woke me right up, but I was crying when I woke up. It seemed a long time to me; I thought I was home a long time, and I cried most all the time. And I know my mamma is dead or something is wrong. (Like many other "prophetic dreams," this one failed to prove telepathic.)

Dreams more or less common to normal adults, as dreams of flying, falling, insufficient clothing, etc., were rare; likewise were dreams of ghosts, fairies, monsters. Most of the dreams were purely visual, and colors were not distinctive. The paralytics, most of whom were crippled from birth, did not make use of the paralyzed limbs in their dreams. I asked a number of epileptics if their convulsions figured in their dreams; the majority answered in the negative. The dreams of the blind feeble-minded should prove interesting, at least as showing extreme simplicity. Unfortunately the mentality of the blind inmates was so feeble that a study of their dreams was impossible. According to Jastrow, the dreams of the normal blind are never visual when the blindness occurs prior to the fifth year.

In general the girls had a more varied dream life than the boys; the girls tended to remember their dreams better, also. These points are quite true of normals. Considering that the feeble-minded have poor memories it might be asked if they remember their dreams well. As far as my experience goes, I find that they recall dreams as well as do normals. As with normals, one will find many who say they never dream; this is, of course, a self-deception, for we have good reason to believe that dreaming goes on all the time we are asleep.

Disorders of sleep, as nightmare, somnambulism, night terrors, were infrequent. Various reasons are ascribed for such disturbances. Some attribute them to physical instigators almost entirely, while others trace them to vivid experiences of an unpleasant nature, mental conflicts, etc. Since dreams are founded on experiences, in which are included thoughts, one must naturally have had before, if in a fantasy only, the experiences which are dreamed. Possibly the comparative freedom of the feeble-minded from worries of one sort or another, their diminished impressionability, feeble imaginations, and the infrequency, as compared with the normal, of repressions and conflicts, may help explain the rarity of anxiety dreams.

Talking in sleep was present in about 8 per cent. While somniloquy occurred generally after the first few hours of sleep, it also occurred directly after going to sleep. In most instances the words said were intelligible; sometimes mumbling went on. As a general thing, but a few words were said at a time, which might be followed in a few moments by more words. One girl would keep on talking for a half-hour or more. The talking dealt almost entirely with daily incidents; rarely of events of long ago. A quarrel during the day, or near bed-time, seemed very potent in exciting sleep-talking, especially in those of an excitable temperament.

Enuresis occurred in about 10 per cent. What is not generally known is that enuresis is in many cases the result of a dream. Enuresis resulting from a dream may occur in two ways: (1) The accumulation of urine in the bladder may give rise to a dream of voiding, and from habit or because waking inhibitions are absent, the desire is fulfilled. (2) In a dream the child may see running water, a urinal, etc., which suggests voiding, which suggestion is carried out. Enuresis is common in the feeble-minded for many reasons. The condition being usually present from an early age, the bladder rarely is able to hold more than a few ounces at a time, and thus does not develop as a result of distention due to restraining the desire to urinate. In mentally normal children enuresis tends to disappear around puberty, due, in part at least, to the better development of the bladder which physiologically occurs at this time and to the better development of the motor-inhibitory centers of brain and cord. The feeble-minded are poorly inhibited; in addition, they suffer from various muscular and nervous weaknesses, and debilitating habits. Even those who are tidy seem unable to restrain the desire to urinate for long, attested by the fact that many awaken at night to make water, and by the celerity with which they seek the urinal. Habit will explain some cases, as it will among children of normal mentality. By training, feeble-minded enuretics may be improved, but when the condition has persisted for any length of time cure is difficult, often impossible. Few will cooperate in treatment, and others suffer from irremovable etiologic factors. By psychotherapy the writer has succeeded in benefiting some feeble-minded enuretics, but only for a time. Usually mentally normal enuretics are neurotic and in poor general health; the condition does not seem to impair the general health of the feeble-minded to any great extent.

From the above sketch it will be seen that the dreams of the feeble-minded are more or less simple in nature. That such should be the case is natural, considering their mental status. The stuff that dreams are made of is the vast amount of material which the mind has been accumulating from infancy; this material includes everything we have experienced, consciously or unconsciously, even our thoughts, all of which is conserved. The feeble-minded have few experiences; they live in narrow worlds; their thoughts are simple. Unlike normal children their imagination is poor, a fact so generally recognized that tests for the imagination are included in practically all so-called mental tests for defectives. Many are unable to read, to comprehend the significance of what is told them in story or other form; they learn by doing, by seeing, not by hearing. For these and other reasons their night-dreams are less varied and less vivid than the dreams of the normal children to whom they are compared.

86 Pinehurst Avenue.

INTESTINAL TOXEMIA—ITS MEDICAL AND SURGICAL TREATMENT.*

By WATERS F. BURROWS, M.D.
AND
ELLIOTT C. BURROWS, M.D.,
NEW YORK.

Intestinal toxemia, or autointoxication, as it is frequently designated, is a common ailment, but owing to its varied symptoms and causative factors, nothing approximating a uniform method of treatment has been followed. It is to be noted that the stomach early in the process is a relatively unimportant causative factor although frequently the sufferer attributes much of his trouble to stomach disease, as a result of the reflex gastric irritation which occurs. In the treatment of the disorder we emphasize the simple colonic and rectal indications for treatment and the few operative measures which have met with success.

The chronicity of intestinal toxemia is due to a persistence of a mechanical or inflammatory lesion in the terminal ileum, colon, or rectum, the consequence of which is a local catarrhal process and interference with complete evacuation of intestinal contents. The latter are more liquefied than normal and their consistency as they pass the ileocecal valve is not adapted to efficient propulsion through the bowel. The intestine contracting upon this semi-

*Read before the Fairfield County Medical Association, Bridgeport, Conn.

fluid mass squeezes some forward and a good part of it backward, leaving residues, where none should exist, throughout the colon and rectum. Mucus appears in the stools in increasing amounts when infection is added to a catarrhal colitis. The lower

colon and rectum may long remain immune and in such cases constipation is present.

The *x*-ray is the method of choice for investigating the function of the ileum, colon, and rectum, while the proctoscopic and digital examination of the rectum and anus are of equal importance. The *x*-ray findings include a dilated or ptosed cecum, insufficiency of the ileocecal valve, exaggerated iliac stasis, kinks and constrictions, irregular filling of the appendix or delay over forty-eight hours in the emptying of it, delayed emptying of the cecum, the hepatic, and splenic flexures, or of the sigmoid, a prolapsed transverse colon, or prolapsed and elongated sigmoid. Normally the bismuth meal begins to collect in the cecum in two hours and is largely out of the small intestines in four to six while the head of the column is at or past the middle of the transverse colon. In ileal and cecal stasis considerable amounts remain in the ileum after six, twenty-four, or even seventy-two hours.

The proctoscope will show a residue in sigmoid and rectum, excessive moisture of the rectal mucosa, pasty, light colored, sour smelling bowel contents which cling to the rectal wall, whereas in health the rectum after evacuation is practically free of fecal particles. Digital examination frequently shows the presence of hemorrhoids, fissures, a tight anal canal, and abnormal sensitiveness of the latter.

The blood pressure is ordinarily reduced, an evidence of adrenal disturbance and involvement of the sympathetic nervous system. The urine gives an increased acidity, occasional trace of albumin, and, with involvement of the ileocecal region and insufficiency of the cecal valve, a marked increase of indican.

We distinguish clinically two types of the disorder—a digestive and a nervous.

In the digestive type the predominant symptoms are general or localized abdominal tenderness and pains. The sigmoidal and cecal regions are sensitive and appendicitis or colitis may be simulated. Tenderness may be very marked over the mesen-

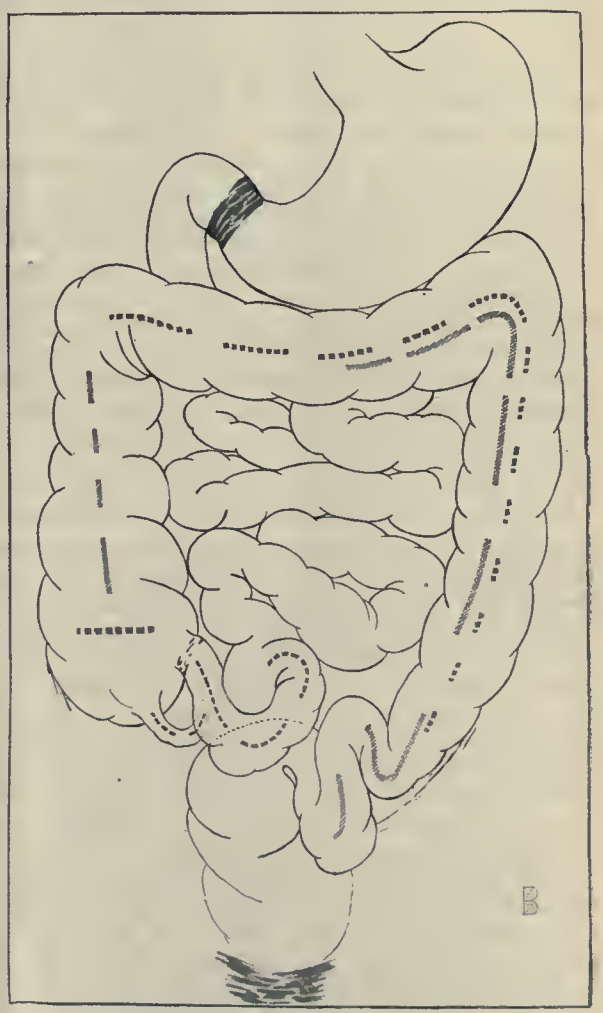

Fig. 2.—Showing the appendix in contact with the terminal ileum—a frequent condition leading to reflex gastric hyperacidity. teric, ovarian, and splanchnic sympathetic plexuses. Irregularity of the bowel evacuations rather than constipation is the rule. However, the *x*-ray examination shows delay in the passage of the bowel contents, as a result of which two or more move-

ments may occur at different times of the day, an indication that at any one time evacuation has been incomplete. We find in such instances large amounts of fecal residue remaining in the ileocecal region and ascending colon, the splenic flexure, sigmoid, or rectum. The *x*-ray may show that the bismuth column has advanced and is partially evacuated within the thirty-six to forty-two hour normal limit, but complete physiological emptying of the bowel from the middle of the transverse colon or splenic flexure is absent. The cecum fails to empty in fifteen to twenty-four hours, and the sigmoid is incompletely evacuated in the morning and becomes elongated and prolapsed. Reflex irritation of the stomach follows. The characteristic symptoms are sick headache, biliousness, gastric distress, heartburn, pylorospasm, eructations of gas, abdominal distention, foul or sour stools, diarrhea or soft evacuations alternating with periods of constipation, and later the symptoms associated with inflammatory lesions of the alimentary tract, gastric ulcer, appendicitis, gallstones, ulcerative colitis. Nutrition suffers, the previous ravenous appetite of many cases of intestinal toxemia is replaced by anorexia; weight may be lost and lassitude occurs. The complexion is sallow, the eyes heavy, joint and muscular pains are present, and disturbances of menstruation and kidney function are common. With the loss of fat and the stretching of ligamentous supports, the uterus, intraabdominal viscera, and kidneys are displaced and nerve reflexes, seen in the nervous type of the affection, result.

With the nervous type of intestinal toxemia abdominal tenderness is frequent, especially over the sympathetic plexuses. The symptoms are fatigue, circulatory disturbances and flushes, irritability and mental depression, neuralgia, indefinite general pains, and backache, and digestive symptoms are always present to some extent. In the examination of these patients the *x*-ray shows a much less marked stasis in the ileocecal region and there is no leakage through the cecal valve, while indicanuria is diminished or absent. The sigmoid, and frequently the colon, is generally elongated and prolapsed. Constipation is the rule. The condition is primarily mechanical rather than catarrhal. Abdominal palpation shows spastic bowel contractions, the sigmoid can be rolled under the fingers and the cecum likewise is firm and contracted in contradistinction to the flabby, dilated organ with splashing contents frequently observed in the digestive type.

In the treatment of intestinal toxemia, outdoor exercises and occupations, and the elimination of worry aid in the reestablishment of normal functions. Proper food reduces intestinal putrefaction and aids in bowel regulation. Food, in the absence of stomach complications, should be liberal in amount and often both nutriment and fluids are forced. Alcoholic beverages are of value in many cases of intestinal toxemia. Water drinking with the meals, stomach atony and ptosis being absent, is advantageous, as is also sweet milk with cream and boiled milk. Buttermilk and the fermented milks are often advocated for periods of two or three weeks at a time. Meat is desirable, but at intervals the diet should be free of both meat and fish.

The direct treatment of the condition consists in:

1. The acceleration of the passage of the bowel contents and the complete evacuation of bowel segments and rectum.
2. The treatment of the catarrhal process.
3. The operative elimination of (a) inflammatory areas in the intestinal tract and (b) obstructive lesions.

All purgatives temporarily relieve, but later increase the symptoms since they injure the intestinal mucosa, increase secretion and the absorption of toxins. Salts are very harmful and always increase the catarrhal process. A vegetable cathartic pill given with the evening meal, gradually reduced in amount, and continued over a period of weeks to obtain one or two formed evacuations in the morning is frequently indicated, but soft bowel movements or irregular evacuations during the day are indications that the bowel is functioning improperly. Enemata irritate the colon. Colonic washings, widely advertised, are pernicious, as are also suppositories and other rectal irritants.

Simple enteritis and colitis are best treated by means of bland substances such as bismuth, barium sulphate, and chalk, injected into the bowel, using olive oil, cotton-seed oil, or castor oil as the vehicles. The medication is injected, through a proctoscope, into the sigmoid flexure, thus avoiding rectal distention, and is spread throughout the colon and cecum by retroperistalsis.

Ipecac, bismuth subcarbonate, subgallate, or salicylate, sodium salicylate, salol, and the tannate preparations are useful medicaments to control bowel consistency and putrefaction, and castor oil or paregoric are indicated at times. Preparations of the Bulgarian bacillus and buttermilk, used for short periods at a time, tend to change the character of the bowel bacterial content. The same is true of yeast. Mixed vaccines of the colon and typhoid types are useful, given in less than immunizing dosage. Organic glandular substances, such as thyroid, thymus, and ovarian extracts, are useless.

The abdomen is kept warm and from time to time an intense skin congestion, which is associated with a beneficial reflex circulatory reaction of the intraabdominal organs, is obtained through means of a thermic or actinic ray lamp. If the *x*-ray shows a ptosed or atonic stomach, or in cases of severe intestinal toxemia with low blood pressure, a proper fitting abdominal belt is ordered.

Few operations are indicated in the treatment of intestinal toxemia. Marked inflammatory or obstructive lesions are, however, definite indications for surgical intervention. The appendix, frequently involved in intestinal catarrh and the common source of reflex gastric hyperacidity and functional disturbance, is always removed provided an abdominal operation is performed, and we consider that it is diseased if a bismuth residue is shown by the *x*-ray in the ileocecal region at the end of seventy-two hours or even forty-eight hours, provided the remainder of the colon is empty. Adhesions, intestinal bands and kinks are sources of reflex irritation and spastic constipation and should be eliminated. Denuded peritoneal surfaces should be swabbed with sterile mineral oil as advocated by the writers in the treatment of certain forms of constipation. Ptosis of the sigmoid flexure is oc-

casionally an indication for sigmoidopexy, but operations upon the stomach, liver, or kidneys to remedy displacement are seldom indicated. Gastroenterostomy is never indicated unless there is an inflammatory or cicatricial obstruction of the stomach outlet, and the worst cases of intestinal toxemia seen in consultation are cases that have undergone such operation, the short circuiting of the intestines or the partial excision of the colon.

Rectal and anal inflammatory or obstructive lesions are indications for operation. Complete bowel evacuations are the secret of health and experience shows that if all back pressure upon the lower bowel is eliminated, through the surgical correction of lesions in the terminal bowel segment, restoration of intestinal functions frequently follows the medicinal treatment of intestinal toxemia.

Hemorrhoids act as both mechanical and irritative lesions. In their removal it is important to draw down any relaxed mucosa, and excise it with the hemorrhoidal mass. The author's operation of "Snare and Bullet" or the "Clamp and Suture" should usually be done under local anesthesia. We do not advocate the clamp and cautery and Whitehead operations. Anal ulceration, fissure, fistula, inflammation of the anal valves and papillæ, and spasmodic or cicatricial constrictions of the anal canal are indications for early operation under local anesthesia. With hypertrophy of the anal sphincters the superficial fibers of the muscles are divided. We have used division in preference to divulsion in over 400 cases of rectal disease.

A study of gastrointestinal functions shows that the stomach will not empty properly provided the food taken hours previously is still largely in the ileocecal segments of gut, and likewise the latter will not freely propel their contents onward when the terminal colon and rectum retain residuals such as are present in chronic constipation and catarrhal conditions of the colon. The accompanying charts show the average *x*-ray findings in health and disease, and direct attention to the three specially developed sphincters or muscular rings which exist in the alimentary tract, namely, the pyloric sphincter, the ileocecal valve and sphincter, and the anal sphincters. These structures, dividing the gastrointestinal tract into gastric, enteric, and colonic segments, protect the processes of digestion. They are controlled by a highly developed sympathetic nervous system and their normal action is easily interfered with by mechanical and inflammatory lesions of the digestive tract, one result of which leads to the symptom complex of intestinal toxemia.

CHRONIC ANILIN POISONING.

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

THE toxic effects of anilins are well known to chemists and those engaged in their manufacture. From time to time, also, they are experienced by those who handle dyed materials or make use of hair dyes containing anilin. The latter group of persons naturally are more subject to chronic than acute poisoning, because the dosage they receive, although small, is continued over a considerable length of time.

The symptoms of this chronic type of poisoning are fairly uniform, although they may develop individually and very gradually. They are interesting because anilin is one of the group of poisons which is quite easily absorbable through the skin, giving rise not only to local but severe constitutional symptoms, which, unless recognized early, may prove fatal, as in the severe acute cases which mainly are derived through inhalation of anilin vapor. It should be noted, also, that wood alcohol often is used as a solvent for anilin.

Among those who may be subject to chronic poisoning through cutaneous absorption are persons employed in dyeing or handling recently dyed furs, wall paper, artificial flowers, calico, and many other fabrics.

The symptoms of chronic anilin poisoning fall under five groups as follows: (1) Cutaneous, mainly intense diffuse dermatitis, becoming exfoliative and very painful, with intolerable burning and itching; (2) gastrointestinal, with nausea, persistent attacks of severe vomiting, independent of the ingestion of food, and diarrhea; (3) nervous and muscular, with vertigo, insomnia, weakness of the legs and a staggering gait; (4) vascular, with a rapid feeble pulse, low blood pressure, cold extremities and cyanosis; (5) ocular, with dimness of vision and diplopœa.

A suit was tried in 1914 in the Supreme Court of Michigan against a dealer who had sold a fur-lined coat with a dyed or blended collar which poisoned the face, neck and hands of the purchaser with anilin. In 1915 the case was reported of a young man, who, while training for an athletic contest, wore gymnasium slippers which were originally white, but he dyed them with a black anilin and acquired severe poisoning (Hartogh).

Numerous similar instances might be cited, but the following personal case is worth reporting in some detail, as the cause of the trouble escaped detection by a number of observers.

The patient, Mrs. "X," of middle age, was a vigorous woman, both mentally and physically. Her symptoms of poisoning lasted for more than two years without explanation. At the outset, while in England, she acquired a dermatitis of the margin of the scalp, parts of the face, neck, and shoulders. The burning and irritation, particularly at night, was so great that she would walk the floor continuously scratching the irritated skin. She consulted a noted practitioner who told her she was "gouty," must give up meat, reduce her diet, take more exercise, etc. The rash, however, kept returning with periodic exacerbation. She then went to a second well-known consultant, who told her she was not gouty but "run down from overwork," due to her social and philanthropic activities, which were really very great. She was told that she needed "building up" and to return to a meat diet, take tonics (not hair tonics!), etc., but the rash continued and extended, amounting to exfoliative dermatitis. This disfigurement in a woman, justly proud of her appearance, was an added source of discomfort. She became greatly worried and suffered from insomnia and anorexia. She then returned to America to seek cure at a noted Spa. Here, she began a course of treatment, but became worse and left for another well-known Spa, where she was given a course of 29 baths, which nearly finished her! The rash extended, from time to time, appearing on various other parts of the body, but always worse on the face, neck, and shoulders. Sometimes after the baths, there would be a universal dermatitis. About this time she had frequent fainting attacks, and her husband several times had to pick her up from the floor, where she had fallen. A physi-

cian, called in, told her she had a "weak heart" and gave her hypodermatic stimulation. She noticed blurring of vision in reading and consulted an oculist. After leaving the Spa she had several severe attacks of vomiting, which were not explainable as they bore no relation to the nature of her food, or other conditions. One of these attacks lasted a full week. She came to the conclusion that she was becoming permanently invalided, that her days of usefulness and activity were over, and became correspondingly depressed.

The history thus far recited covers a period of about two years. Upon her return to New York I was called to see her, and having known her well in previous years, noticed a remarkable Titian red color of her hair which I did not associate with her previous appearance. I happened to recall a photograph which Dr. John A. Fordyce had given me, of an exfoliative dermatitis on the hands of a barber, produced by continually rubbing in hair dye. I accused her of the use of dye, and after the customary battle, where such an obnoxious subject is broached, her maid produced a bottle, or rather two bottles, one containing a mordant to be used with the dye. It was a French preparation, and I was informed by the patient that it was the only one which she had found to produce the desired "Titianesque" effect. As she was skeptical about the nature of the poison, I said I knew it must contain anilin, for she had all of the typical symptoms of chronic anilin poisoning, namely, vertigo, gastritis, diplopia, asthenia, and an exfoliative dermatitis. I said, however, that we should have the preparation analyzed, as I could not tell which anilin it contained. It was therefore sent to an expert chemist who promptly telephoned to the patient that she was endangering her life by its use, and to stop it immediately; that several German chemists had died of anilin poisoning from the hazard of manufacturing this form of anilin, and that its further production in Germany had been interdicted. Now, I had previously told the patient, when she asked what she would do, merely to let her head alone and put nothing upon the hair, not even water, because water greatly intensifiies the irritation of the poison, in part through spreading it over the surface. She became so alarmed, however, by the report of the chemist that she got into a tub and proceeded to wash her hair to get rid of the poison. The effect of this was to make her look as if she had scarlatina. By this time she was so thoroughly alarmed that she agreed to abide by instructions, and within a week there was marked improvement, and within three or four weeks the local symptoms had all practically disappeared, and her general health was greatly improved. About this time, however, she had one further mishap which was amusing. I had warned her, that having irritated her skin for more than two years, she must expect to find that very slight causes of irritation might produce a moderate return of the rash, and this was illustrated by the following episode: upon being called to see the patient one day I found a slight recurrence of the rash behind the ears and at the sides of the neck. I asked what she had been doing the evening before, and she pointed to a table by which she had been sitting, smoking cigarettes, while in evening dress. On the table was a so-called "smoke consumer" which contained a perforated platinum cap, over an alcohol flame. On igniting the alcohol the platinum becomes red-hot and continues partially to consume alcohol vapor, after the flame is blown out, thereby producing formaldehyde, which to some extent, seems to deodorize tobacco smoke. Persons with sensitive integument are easily irritated by this vapor. I explained the trouble to her and she threw away the "smoke consumer," saying, "What I really need is a resident chemist to live here and save my life!"

The patient has remained entirely well for a long time since this final episode and has learned to be as proud of her grey hair as of the Titian red! The preparation she used is called "Goute à Goute" (drop by drop), because, in mixing it for application, additional drops are used to obtain the dark shades, up to almost jet black. The type of anilin was paraphenophendiamin 2 per cent. with hydrogen peroxide 75 per cent. and alcohol 23 per cent.

Some time later a well-known oculist told me that my recital of this interesting case had enabled him to make a correct diagnosis in the case of a woman who had great irritation around the eyelids and of the conjunctivæ. For some time she had been using a similar anilin hair dye and various forms of treatment had failed to relieve the irritation about the eyes, until she discontinued the dye, when it immediately disappeared. Quite recently I have learned of another case in a woman who had a more violent general exfoliative dermatitis from the same cause.

The experience of Mrs. "X" indicates that the menace of anilin hair dyes has not yet sufficiently been emphasized to be appreciated generally by the medical profession. The fact that personal susceptibility varies as much as in the case of poisoning, for example, by *Rhus toxicodendron,* only makes it the more difficult always to recognize such cases as those herein reported. The bottle used by Mrs. "X" contained a warning on the label to discontinue the use of the preparation if it irritated the skin, but this had been overlooked entirely by her. It also bore the legend: "Guaranteed by the Pure Food and Drugs Act." I wrote to the authorities in Washington to ascertain the interpretation of "guaranteed" in relation to purity of drugs and was informed that it merely was a guarantee that the preparation contained what it was advertised to, not that it was especially injurious, and that much confusion had arisen over this fact. Recently the New York City Department of Health has prohibited the sale of toxic hair dyes, but nevertheless it is well to be suspicious of artificial Titian red and all the darker shades up to jet black.

61 West Forty-ninth Street.

Medicolegal Notes.

Physician's Charges.—In an action by a physician for professional services and for room, board and nurse hire, in which the defendant brought a cross-action against the plaintiff for malpractice, the plaintiff was held entitled to recover the reasonable value of the use of the room, and board and nurse hire, regardless of whether he exercised ordinary care and skill in the defendant's treatment. In the cross-action an instruction was held erroneous which permitted the jury to apply its own standard of care, or that of each individual juror, to the treatment accorded the defendant by the plaintiff, and which completely ignored the test fixed by law based upon the methods and practice of the school of medicine to which the plaintiff belonged.—Dameron v. Ansbro (Cal.) 178 Pac. 874.

Expert Evidence—Fracture Cases.—In a cross-action for malpractice, the exclusion of a question asked a physician on cross-examination, intended to show that there was no bony union in the fracture which a doctor had rebroken was held error; the question being calculated to test the competency of the witness and discredit his statement on direct examination that he had found such osseous callous. Whether a physician called as an expert witness be permitted to illustrate his testimony by means of a human skeleton is held a matter left to the sound discretion of the court, but where its use could not have aided the jury, denial of permission was not abuse of discretion. It is held that only an expert could properly determine and testify as to the nature of the treatment and required amount of force that might be exercised to break adhesions in fractured bones, but a requested instruction, implying that only an expert could testify as to the amount of force that was actually used was properly refused. —Dameron v. Ansbro, (Cal.) 178 Pac. 874.

THE RELATION OF GLYCOGEN TO DIABETES AND ACIDOSIS.

As a result of some of his observations, Ervin has constructed an ingenious and interesting theory (*Jour. Lab. & Clin. Med.*, 1919, v, 146) as to the manner in which the inability of the diabetic organism to synthesize glycogen reacts upon the body. His experiments seem to show that the presence of glycogen in a fat-protein emulsion tends to stabilize it and to protect it against the breaking action of acids, salts, etc. Further, in a glycogen-fat emulsion neither the glycogen nor the fat will react to the dyes usually used to stain them. This fact has in the past led to the belief that fat and glycogen exist in the tissues in inverse ratio to each other. In the liver in phosphorus poisoning, for instance, it has been observed that there is a decrease in the glycogen content as accumulation of fat develops. Chemical estimation of the fat in fatty livers has show that the actual content of fat may be less than normal. Ervin explains this apparent paradox by the theory that in the normal cell the fat exists in the form of a stable emulsion with glycogen and therefore does not stain. In phosphorus poisoning the glycogen is gradually hydrolyzed out and in the absence of its protecting influence the emulsion is broken and the fat is readily stained and so *appears* to have accumulated in the cells.

In diabetes there is apparently an inability on the part of the body to synthesize glycogen, and glucose accumulates in the blood. The body stores of glycogen disappear and as a result not only is the fat taken in the food emulsified with difficulty, but the emulsions already present are rendered less stable. In this way the margin of safety is obliterated and any slight accident may upset the balance and an overwhelming load of fat be delivered to the cells. This excess of fat is not burned completely and a condition of acidosis results. Ervin claims that it is only by some such theory that Lusk's finding of an increased metabolism in diabetes and phosphorus poisoning can be explained.

On the basis of this theory he recommends that in those poisonings which result in acidosis and fatty degeneration, such as mercury, phosphorus, and chloroform, the patient should first be alkalinized and then fed an abundance of carbohydrates so that he may be able to build up a stable protein-glycogen-fat emulsion that will stand up against the action of the poison. In diabetes, of course, this is not possible for the body is unable to build up glycogen, no matter how great may be the supply of glucose. It is a very interesting theory and in some phases is susceptible of experimental proof. It is hoped that the author will continue his work along this line.

HEMIC CYSTS OF THE SPLEEN.

AMONG the hemorrhages arising after traumatism of the spleen, those causing great loss of blood and producing death from peritoneal inundation belong to imperative surgery. But there are other sanguineous collections, less extensive than the foregoing, which develop into hematomata and on being walled off give rise to hemic pseudocysts of the spleen. In a great many cases, probably the large majority, the spleen giving rise to hemorrhage is the seat of pathological changes resulting from malarial infection, and contrary to what is observed in splenic rupture in which the trauma was extremely violent, in the process under consideration the force acting on the left hypochondrium is occasionally very trifling. The seat of these sanguineous collections may be intrasplenic in the midst of the parenchyma, or else perisplenic. The walls of the cyst are formed of adult fibrous tissue, and no endothelial element can be detected—an important characteristic which differentiates hemic pseudocysts of the spleen from serous cysts of the gland, the contents of which may be bloody.

The evolution of an intrasplenic blood cyst differs from that of a perisplenic hematocele. The former presents in its evolution two stages: in the phase of hematoma there is pain in the left hypochondrium with a poorly defined tumefaction of this region. In the second stage, that of encystment, the tumefaction is replaced by a cystic tumor with thick, smooth walls, painless and fluctuating. A perisplenic hematocele is characterized by its rapid development, enormous extension, and an aspect resembling a malignant neoplasm.

The diagnosis of the process under consideration is somewhat delicate; it is based upon the location and characters of the cystic tumor occurring some little time after a relatively slight injury. To make a differential diagnosis between a blood cyst and certain types of malignant neoplasms having a cystohematic evolution is a matter of some difficulty. The hemorrhagic ascites, rapid development and extension, and generalization of the growth, with a recurrence following surgical interference, are in favor of sarcoma. But it should not be forgotten that a perisplenic hematocele has been known to assume the same clinical picture.

The treatment of hemic cysts of the spleen is surgical, but should be conservative. According to circumstances, simple incision and drainage may be all that is required, but when the subcapsular cyst

is not very adherent it can be completely or partially excised. When the spleen has undergone marked pathological changes, splenectomy should be done.

IS PEDIATRICS A SPECIALTY?

THERE is an idea abroad among moral men (to quote Josh Billings) that when pediatrics calls itself a specialty, pediatrics is putting on airs. Why, it is asked, are the care and feeding of children subjects too mysterious for the well-trained internist to master? Why must a doctor keep his hands off older people in order to treat children properly? Why must he refuse to treat children in order to do justice to their elders? These questions assume significance when an internist with a bent for children's diseases comes to decide whether or not he shall practise one to the exclusion of the other.

Now we all know internists whose ability in the field of children's diseases is unquestioned. In the treatment of our own children we should probably give them preference over many who call themselves pediatrists. But for the difficult, intractable cases, it is the men who have had years of intensive training in children's diseases (which cannot be made a side issue to a training in general medicine) whom we are glad to call in consultation. It is they who are selected to teach pediatrics in the schools. Taking an analogy from the surgeons, there can be no objection to a man well trained in general surgery doing a tonsillectomy. But other things, such as intelligence and industry, being equal, the man who is kept busy doing only tonsillectomies will do the better operation. We should probably like to have him remove our own tonsils. All this seems too obvious to warrant reiteration. But the entire profession seems to have its fingers in the pediatrical pie. Even those who profess and call themselves surgeons are often to be found feeding and treating their patients' offspring.

The question seems to clarify itself as follows: Nobody who professes to be a specialist in anything else should meddle with the medical diseases of children. If he does, he is doing his specialty (not to mention his patients) an injustice. The only proper exception to this is the internist—commonly known as the medical practitioner. Pediatrics is a branch of internal medicine. There is nothing to prevent a good internist from doing creditable work in children's diseases. But certainly the man who poses as an expert in pediatrics should let adults alone. In any case, let no internist lay the flattering unction to his soul that he is qualified to cope with any and every pediatrical contingency which may arise, or that the pediatrists are superfluous. Pediatrics is a specialty and will remain so.

ENDEMIC SLEEPING SICKNESS.

THE affection known as encephalitis lethargica, which has heretofore appeared in epidemic incidence with influenza now seems to have become a domestic evil and it will occur to the reader that here may be the makings of future epidemics. Lhermitte, in an original article in the *Journal de médecine et de chirurgie pratiques* (October 10, 1919, xc, 19) notes amid endemic incidence all over the world a lack of identity in the clinical picture with the exception of the feature of hypersomnia. It will be recalled that before this affection asserted its autonomy, we had numerous other morbid states known variously as narcolepsy, lethargy, hypersomnia, complicating various severe illnesses, etc., and this should put us on our guard against reporting something old as a new form of illness. In true encephalitis lethargica there are four cardinal symptoms: ocular paralyses, hypersomnia, fever, and the general state. The ocular paralyses may be absent at the outbreak of the disease, but once present they are characteristic. So, too, is the type of hypersomnia. It is a narcolepsy, but the subject does not arouse quickly, as in the condition which commonly goes by that name and in which the seizures may be only momentary. However, the permanent sleep may be preceded by brief narcoleptic crises. During the night the patient is not distinguishable from an ordinary subject who is sound asleep. The state of the extremities during the sleep suggests hypertonus of the muscles and recalls catatonia and catalepsy. With this rigidity is also seen in some cases tremor which gives a picture like paralysis agitans. Other deep-seated organic nervous affections are more or less simulated. The temperature goes to 104° F. and the subject naturally becomes asthenic. In this affection a Wassermann test and examination of the spinal fluid should always be made. Of great interest are the mild, abortive forms, for these undoubtedly exist and are overlooked. The author, who has had considerable experience with lethargic encephalitis, does not describe any of the latter type, and it must be difficult to make the diagnosis in the absence of specific finds.

THE VOLUME OF THE HEART.

IT is very simple to measure the volume of the heart at autopsies and to calculate an average volume for the adult or child heart but these figures give ur an imperfect idea of the volume during life. Navarro, in the *Revista Española de Medicina y Cirugia* for November, 1919, ii, 17, calls attention to the defects of the clinical methods now in use, and of the superiority for this purpose of radiography. The method of orthodiagraphy is difficult and dangerous and he prefers calculating the ratio of the volumes of the heart and thorax. The subject lies on his face, and by using a technique based on that of Kreussfuss, the author finds that the normal heart is 44 per cent. of the transverse diameter of the thorax. To this 44 per cent., 21 per cent. should be added for the intervening pulmonary tissue to the left and 35 to the right, which accounts for the total 100 per cent. To obtain measurements for the individual as distinguished from the average heart the author has devised a radiocardiometer based on the graphic method of squares as applied to the shadows of the separate segments of the heart and extracardiac tissues. The device is intended in reality for clinical purposes, since it should be a simple matter to state the exact degree of hypertrophy or dilatation of one ventricle or the

entire organ in diseased conditions. Such results would be useful to check up those obtained by ordinary physical diagnosis.

Sodoku.

When it was first learned that rat-bite fever could exist in Europe not a few articles appeared on the subject, but of late it has not received much attention. In *Il Policlinico* for October 10, 1919, xxvi, 42, Bergamini reminds his readers that Frugoni, an Italian, was the first to recognize sodoku in Europe. The affection in many respects recalls recurrent fever and likewise syphilis, both of which are spirochetoses, and the Japanese appear to have shown the spirochetic nature of endemic sodoku. Spirochetosis icterohæmorrhagica is also allied to sodoku in some respects, for the rat is certainly a carrier, that is to say, a reservoir for the spirochete of this disease, even if it does not transmit it. The author reports a case of sodoku in detail in which the following were noted: bite of a rat, cyclic fever, enlarged lymphnodes, exudative erythema, recurrent type of symptoms as in syphilis, permanently enlarged lymphnodes as in syphilis, total absence of other morbid features, sterile blood; positive Wassermann (four plus) as in syphilis; cure by salvarsan as in syphilis. Does the rat which gives the disease have the disease? This is conjectural, for in the European cases at least there has been no chance of catching the offending animal. If it does have the disease the latter is perhaps contagious only during a recurrence of the symptoms.

News of the Week.

The Women's Medical Society of New York State. — The Fourteenth Annual Meeting of the Women's Medical Society of New York State will be held at the Hotel McAlpin, New York City, March 22, 1920. All women physicians are invited. There is a very interesting program provided at both the morning and afternoon sessions. Among the speakers will be Dr. Winifred Cullis of London, England. At luncheon the members of the State Society will be the guests of the Women's Medical Association of New York City. Dr. Josephine Baker of the Department of Health will be the toastmistress at the banquet that evening.

"D" Telephone Numbers for Doctors.—The recently organized Doctors Service Corps, New York City, has sent letters to the New York Telephone Company, to Dr. Copeland, Health Commissioner, and to the Public Service Commission for the Second District, suggesting the use of a large-sized letter "D" to be prefixed to the telephone number of every physician, surgeon, and dentist in the city. A similar mark should be placed over such number at the various operating station switchboards, in order to insure the most efficient service possible on these priority calls, and to eliminate the possibility of fictitious "doctor calls."

Conference of Pennsylvania Department of Labor and Industry. — On Thursday, March 25, 1920, the Department of Labor and Industry will hold its Tenth Conference of Industrial Physicians and Surgeons in the State Capitol at Harrisburg. This conference promises to be of unusual interest as it will be the final day of a four-day Safety Congress held by this Department in which speakers of international prominence will participate.

Police Hospital Plans Halted. — After pledges for $160,000 had been secured toward building and equipping a hospital for the exclusive use of the police of Greater New York and their families, Police Commissioner Richard Enright called a halt on the project. No official explanation of this action was made.

American Medical Editors Association.—The fifty-first annual meeting of the American Medical Editors Association will be held at the Grunewald Hotel, New Orleans, Louisiana, Monday and Tuesday, April 26-27, 1920. This is the week of the American Medical Association. Dr. Seale Harris of Birmingham, Ala., is president, Dr. Charles Chassaignac is local chairman, and Dr. J. J. Wymer, 1216 Maison Blanche Building, New Orleans, is chairman of the committee on hotels.

Three Million "Chronics" in United States.—According to Dr. F. C. Wells, Medical Director of the Equitable Life Assurance Society, there are three million persons in this country who are "continually sick." Thirty-three per cent. of the young women are physically deficient, and sixty per cent. of the boys and girls are physically impaired.

Diphtheria in New York City.—Between January 1 and 25 there had been reported 2,873 cases of diphtheria, as compared with 2,496 cases during the same period last year. This increase, in the opinion of Dr. Royal S. Copeland, Commissioner of Health, is not enough to warrant the report of a diphtheria epidemic.

St. Louis Skin and Cancer Hospital Elects New Officers.—J. Lionberger Davis was elected president of the St. Louis Skin and Cancer Hospital at the recent meeting of the Board of Directors. Other officers elected were: James M. Franciscus, first vice-president; Frank V. Hammar, second vice-president; H. D. Condie, third vice-president; J. H. Farish, treasurer, and Daniel K. Catlin, secretary. Horace M. Swope was appointed chairman of the board. During the past year the hospital rendered 12,495 hospital days' service as compared with 11,339 in 1918. Dr. Martin F. Engman is chief of the medical college staff of the institution.

Gifts to Medical Schools.—The General Education Board of the Rockefeller Foundation has announced the following contributions for the advancement of medicine: $150,000 to Washington University, St. Louis, Mo.; $400,000 to Johns Hopkins University, Baltimore, Md., and $150,000 to the Meharry Medical School, Nashville, Tenn., for the training of negro physicians.

Nursing Drive.—A campaign to raise $1,000,000 to extend the visiting nurse service of the Henry Street Settlement, New York City, will be conducted March 15 to 22. Paul D. Cravath is chairman of the campaign committee.

Chicago Speedway Hospital. — The proposed purchase and completion of the Chicago Speedway Hospital was apparently settled when the House

recently agreed, 106 to 24, to increase by $400,000 its appropriation of $3,000,000 for Government acquisition. This is $100,000 less than was provided by the Senate in the Deficiency Appropriation bill, but supporters believe final settlement is near.

Alcoholic Wards Empty.—Bird S. Coler, Commissioner of Public Charities, New York City, reports that the alcoholic wards in the Department of Public Charities and Bellevue and Allied Hospitals are practically idle as the result of prohibition. Most of the floors of the Municipal Lodging House are being closed, the place having more employees than patrons.

Whiskey on Federal Fair Price List.—At a recent conference in Chicago, attended by Harry Mager, Collector of Internal Revenue, District Attorney Clyne, Hubert Howard, State Prohibition Commissioner, and A. A. Sprague, head of the Illinois Fair Price Commission, it was decided to place whiskey for medicinal purposes on the fair price list. The price was not decided. Druggists, it was stated, were charging as much as $24 a gallon for whiskey that might be sold for $5 a gallon.

Service Men's Dentist Bills Paid by Uncle Sam.—If satisfactory evidence is offered that his teeth decayed while he was in uniform, the ex-service man's dentist bill will be paid by the Government, according to recent announcement by Captain R. Rexford Shaffer, supervisor of the New York State branch of the War Risk Insurance Bureau.

Emergency Hospital Aid.—The United Hospital Fund of New York City has distributed $400,000 of the proceeds of its fall campaign among forty-six member institutions. The usual yearly distribution of the fund is made in May, but this emergency apportionment was made because of the urgent needs of the institutions at this time. Under the preliminary distribution St. Luke's receives $27,850.90, Mount Sinai $27,752.32, New York $23,118.26, Presbyterian $18,472.12, Lincoln $16,567.90, Lenox Hill $14,409.42, Roosevelt $13,318.92, Post Graduate $11,868.72, French $6,789.28, Flower $5,945.54, and Hahnemann $3,649.32.

German Students Resent Professor's Protest for Belgium.—Dr. Nicolai, Professor of Physiology in Berlin University, who, in 1914, protested against the violation of Belgium's neutrality, for which he suffered many indignities, including the loss of his professorship, the confiscation of his property, and imprisonment, has again met with ill-treatment. He was reinstated in his professorship last year, but it is reported that 90 per cent. of the students are violently militarist and nationalist, and they refuse to give Dr. Nicolai a hearing, demanding his resignation. His book, "Biology of War," which was written during his imprisonment, was recently burned in front of Berlin University, the students dancing around the bonfire. He has received letters threatening the fate which befell Liebknecht, Eisner, and Haase. He has been offered professorships by two universities, one in Geneva, Switzerland, and the other in an entente country, the name of which is not stated in press dispatches.

Milk Exports.—The National City Bank has recently compiled condensed milk statistics showing that $120,000,000 worth of this commodity was shipped to Europe during the last five years.

"Movie" X-Rays.—According to announcements from Paris a combination *x*-ray and moving picture apparatus has been invented by Dr. Lormon and Dr. Comandon. With this apparatus pictures of animals can be thrown on the screen and the movements of the various organs shown. Modifications of the apparatus, making it applicable to human beings, will doubtless be forthcoming.

Medicines to Italy.—The American Free Milk and Relief for Italy, it is announced, will extend its activities to include the sending of medicines, clothing, cereals and cod liver oil to the sick and destitute orphans and children of Italy.

"Save the Children" Congress.—Twenty countries were represented at the "Save the Children" Congress which convened in Geneva, Switzerland, on February 26. Farmer Murphy was the American delegate. German representatives, according to press reports, predominated.

The Pope's Relief Fund.—It is announced that on February 21 the Pope's subscription for the relief of poor children in Central Europe had reached 5,000,000 lire.

Doctors Raise Fees.—Members of the West Side Physicians' Business League, Dayton, Ohio, recently voted to raise their rates to three dollars for day calls, five dollars for night calls, and one dollar for telephone consultations. Physicians in other parts of the city, as well as of the county, according to press reports, disclaim having taken similar action.

Southard Memorial Service. — The faculty and students of Harvard University recently held services in memory of the late Dr. Elmer E. Southard, Assistant Professor of Psychology in the university and Bullard Professor of Neuropathology at Harvard Medical School. The services which were held in Appleton Memorial Chapel, Cambridge, were attended also by representatives of the National Research Council, the State Board of Health, and other bodies with which Dr. Southard was identified.

Osler Memorial Meeting.—A meeting in memory of the late Sir William Osler, Regius Professor of Medicine at Oxford University, was held at the New York Academy of Medicine February 28. Dr. George David Stewart, President of the Academy, presided and introduced the speakers, Dr. William H. Walsh of Baltimore, Dr. Thomas McCrae of Philadelphia, Dr. Francis J. Shephard of Montreal, and Dr. Edward C. Streeter of Boston.

Red Cross Workers in Europe.—According to a statement recently issued by Lieut.-Colonel Robert E. Olds, Red Cross Commissioner for Europe, more than 1,000 Red Cross workers are still engaged in relief work in Europe. In Paris a large force is maintained to direct the work of commissions in the following countries: France, 28; Albania, 65; Czechoslovakia, 3; Greece, 5; Italy, 29; Montenegro, 44; Poland, 131; Rumania, 29; Serbia, 96; West Russia, 54; South Russia, 25; England, 5; Vienna, 12.

Colonel H. D. Thomason, Medical Corps of the Army, recently retired, has assumed the duties of Superintendent at Flower Hospital, Sixty-fourth Street and Avenue A, New York City.

Dr. Ruth A. Guy of New York City is now director of a new American Red Cross hospital for babies in Elbasan, Albania, according to a recent report received by the Atlantic Division.

Charitable Bequests.—By the will of the late Charles G. Thompson of New York City six institutions will receive at least $6,000,000, constituting the residuary estate. The institutions named are Columbia University, the New York Historical Society, the New York Hospital, the Presbyterian Hospital, the Association for Improving the Condition of the Poor, and the Children's Society.

If the estate of the late Archibald H. Bull of Elizabeth, N. J., exceeds $2,000,000 after the payment of all taxes, the beneficiaries are to receive bequests just double those provided for in the will. Among the bequests provided are: The Elizabeth Home for Aged Women, $25,000; the Elizabeth Orphan Asylum, $25,000; the Visiting Nurse Association and Charity Organization Society, Elizabeth, $10,000; and the Egenolf Day Nursery, $1,000.

Obituary Notes.—Dr. ARTHUR BROWNELL WRIGHT died at his home in Hartford, Conn., February 4, at the age of 51. He was graduated from the College of Physicians and Surgeons, New York, in 1895.

DR. FRANCIS C. PHILLIPS, an expert chemist, died of influenza-pneumonia at his home in Pittsburgh, Pa., February 16, at the age of 69. He had been professor of chemistry in the University of Pittsburgh for forty years.

DR. FREDERICK SCHOENENBERGER, a Police Department surgeon, New York City, died in Roosevelt Hospital February 20, following an operation for gallstones. He was born in 1875, and was graduated from Bellevue Hospital Medical College in 1896. He specialized in urology, and was adjunct professor of urology in Fordham University School of Medicine. Dr. Schoenenberger was a member of the American Medical Association.

DR. RAYMOND J. HAUSER, Lieut. M. C. U. S. A., of Danville, Pa., died of bronchopneumonia at Camp Grant, Rockford, Ill., on January 18, 1920. He was 33 years of age and was a graduate in medicine of the University of Pennsylvania in 1910. He had served one year in France and one year in Camps Dix and Greenleaf.

DR. HARRY J. TATE of Pittsfield, Mass., newly elected city physician, died of pneumonia in the House of Mercy Hospital, February 11. He was 30 years of age, and was graduated from the George Washington University School of Medicine, Washington, D. C., in 1914. Dr. Tate served as first lieutenant, M. R. C., with the Berkshire Ambulance Corps, enlisting in July, 1917. He spent a year overseas, and was promoted to captain in the 301st Ambulance Company. He was first commander of the Pittsfield Post, American Legion, a member of the Massachusetts and Berkshire Medical Societies, and was affiliated with various other organizations.

Dr. ROBERT C. FORSYTH of Kirkwood, Mo., died of influenza in St. Luke's Hospital, St. Louis, February 8. He was forty years of age, and had practised in Kirkwood for sixteen years. He was graduated from the Washington University Medical School in 1902. He was a member of the American Medical Association and various local societies.

Dr. WILLET J. HERRINGTON of Bad Axe., Mich., died of pneumonia February 10, in his sixty-first year. He was graduated from the University of Michigan Medical School in 1882, and for fourteen years was directing surgeon of the Hubbard Memorial Hospital in his home town. He was a member of the American Medical Association and other organizations.

Dr. ALBERT M. DUNLAP of Cleveland, Ohio, died of pneumonia February 12, in his thirty-eighth year. He was graduated from the Cleveland College of Physicians and Surgeons in 1905, and served as lieutenant in the Medical Reserve Corps during the war.

Dr. WILLIAM C. HASSLER, San Francisco health officer, died of influenza, in that city on February 11. He fell victim to the disease while leading the campaign against influenza in the recent epidemic. Dr. Hassler, who was born in 1868, was graduated from Cooper Medical College, San Francisco, in 1892. He was a member of the American Medical Association.

Dr. EMORY LANPHEAR of St. Louis, Mo., well known surgeon of that city, died of apoplexy at his winter home, Tampa, Fla., February 6. Dr. Lanphear was born in Mitlis, Turkey, in 1859. He received his early education at Hartford Institute and Kansas State Normal School and was graduated from Missouri Medical College (Washington University), in 1881. He continued his studies in various medical colleges in this country and abroad and held professorships at the University of Kansas City, University Medical College, Kansas City Medical College, St. Louis College of Physicians and Surgeons, and many others. He retired from active practice two years ago on account of ill health.

Dr. JOHN A. HUNT of Taunton, Mass., died of cancer February 13, at the age of 65. He was graduated from Boston University Medical School in 1893.

Dr. PHILIP THOMAS KENNEDY of Hartford, Conn., died at St. Francis Hospital in that city on February 14, following an operation for pulmonary abscess. He was born in 1883, and was graduated from the Medical School of Harvard University in 1909, specializing in pediatrics. He held various hospital connections, and was a member of the American Medical Association and various State and local organizations.

Dr. GEORGE W. BROWN of Pratt City, Ala., died February 22, at the age of 62. He was graduated from the Atlanta Medical College in 1877, and had practised in Pratt City for thirty-five years. He was a member of the American Medical Association.

Dr. ELISHA PRICE MERRITT of Atlanta, Ga., died of pneumonia February 15, at the age of 35. He was graduated from the Atlanta School of Medicine in 1912.

Dr. FRANK H. WHITTEMORE, of New Haven, Conn., died of pneumonia February 26, at the age of 65. He was graduated from Bellevue Hospital Medical College in 1874.

Dr. WILEY A. JONES of Cantril, Iowa, died February 17, at the age of 79. He had practised medicine in the vicinity for nearly fifty years.

Correspondence.

WOULD THE INTRASPINAL INJECTION OF A SOLUTION OF CALCIUM SALTS "CAUSE INSTANT HEART-BLOCK?"

To the Editor of the Medical Record:

Sir:—An article by Dr. John Aulde, entitled "Applied Calcium Therapy," which appeared in the issue of the Medical Record for February 14, contains the following statement:

> Some ten or twelve years ago I had a chat with Dr. Meltzer regarding the remote effects of magnesium sulphate introduced into the spinal canal for the relief of tetanus. I asked him if it would be the proper procedure, in case evidences of collapse appeared, to administer calcium salts, to which he promptly replied that it would cause instant heart-block, so that accounts for the physiological antagonism.

This statement was a surprise to me; I have no recollection of ever making it to Dr. Aulde or to anyone else. I do not state it in a sense of denying Dr. Aulde's statement. The negative effect of my not remembering the "chat" would be insufficient to support my claim; Dr. Aulde may be fortunate to possess a better memory than I. But I wish to state emphatically that *I never gave expression to the view, that the intraspinal administration of calcium salts "would cause instant heart-block"*; moreover, I could not have put forward such a claim, since we never made experiments which would justify us in making such a far-reaching positive statement. In the first place, the discovery, that by intravenous injections calcium rapidly abolishes the paralytic effects caused by an overdose of magnesium, does not apply to the intraspinal method; to our disappointment, spinal application of a calcium salt does not interfere with the developed paralytic effects of the overdose of magnesium. This I have repeatedly emphasized in the lectures on the treatment of tetanus by intraspinal injections of magnesium.

Furthermore, it is true that in recommending the intravenous injection of calcium for treatment of paralysis due to the administration of an overdose of magnesium salts, I especially emphasized that the dose of the solution of calcium salts *must be only moderate,* since large doses of calcium following injections of magnesium may prove to be deleterious for the heart. This warning is based upon many incidental experimental observations. But they were made only in recent years and the nature of the deleterious action was not yet studied experimentally.

I am therefore sure that I could not have said "ten or twelve years ago" that the deleterious action of an intraspinal injection of a solution of calcium salts would cause instant heart-block.

S. J. Meltzer, M. D.
Rockefeller Institute for Medical Research.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, February 13, 1920.

Influenzo-pneumococcal and Influenzo-Streptococcal Septicemia.—Dr. Herbert French, Physician to Guy's Hospital, gave a lecture at that hospital on January 30 on influenza, particularly dealing with that of a septic type. French has had a great deal of experience of influenza during the epidemics which occurred in Europe and in England within the past two years, experience gained for the most part in large army camps and in soldiers' hospitals. Some of the findings and conclusions of himself and colleagues are interesting and perhaps differ in important details from those usually recorded. As in all countries, the outbreak of the pandemic in England was generally speaking distinguished by the mild nature of the type. The second outbreak, however, was marked by its high rate of mortality, there being more people killed by it than perished in the course of the entire war, possibly as many dying of it among the forces in Europe alone as were killed in the war. In connection with this high death rate French points out a somewhat peculiar fact and one that does not appear to be generally recognized, namely, that out of one thousand cases of influenza only about two hundred were of the pneumonic type but these were of so extremely virulent a character that they increased the death rate to such a degree that they conveyed the impression that the majority of influenza cases were of the type. Moreover, the pneumonic form did not conform to one type of pneumonia, and although there was a general similarity, different kinds of inflammation were seen. Bronchopneumonia was usually a feature, but by no means always, nor was lobar pneumonia so frequently present as it is believed to have been. Sometimes inflammatory edema-like results were produced of the nature of that supervening on chlorine gas poisoning. In fact the disease was a mixed lesion for which no appropriate name exists, but for which French suggests the name of pneumonitis.

Of all the characteristics of the "pneumonic" cases most stress must be laid on the color of the patient. As a prognostic sign the color is the most trustworthy. The patient may be sallow or white of color or flushed or sunburnt or plethoric, but whatever the degree of the color of the face it is a most hopeful symptom when it remains red. The face may be sallow with the lips and ears alone red, or the patient may be of a rubicund type with general redness of the whole face, or the face may be flushed with the unnatural redness of fever, so long as his lips and ears present a red hue, there is good hope for recovery, no matter what the lung signs, the temperature, the pulse rate, or the respiration rate. On the other hand, when the color of the patient's face, the lips and ears in particular, is of heliotrope or lavender or bluish tint, the outlook is very grave even though in all other respects the patient seems to be progressing favorably. The color then is the surest basis on which to pick out those cases which are likely to end fatally in a day or two from those who, unless a change comes and the patients themselves develop along the same lines later on, will most probably end in recovery. While it is not impossible for a "heliotrope cyanosis" patient to recover it is extremely rare. At one time it was thought that the color might be due to methemoglobinemia, but the spectroscope shows no abnormal pigment in the blood in these cases, nor is there any defect in the oxygen-carry-

ing capacity of the blood; the condition is one apparently of what Professor Haldane has termed "anoxemia" similar to what has been seen in gassed cases at the front and probably due to analogous causes, judging from the histological changes seen in the lungs. It was shown that the condition of the heart had no relation to this color. A man might die and his pulse rate be good half an hour before death. Venesection was of no avail, and if the cyanosis had been due to the heart venesection would have given relief.

Another somewhat distinctive sign of these pneumonic cases is that, as in typhoid fever, many of the former cases give out a faint indefinite smell. It is not the sour smell of perspiration, nor is it merely fetor from the coated tongue or the sordes that is apt to collect on lips and gums. It could not be called pathognomonic. but it has seemed worth while to call attention to it.

Of the post mortem findings with regard to the histological changes in the lung tissues, the most notable are the following: In many sections of the lung tissues there is an appearance in and around the bronchioles and inside the alveoli which at first gives rise to the thought that the paraffin has been imperfectly removed from the specimen. On further testing it seems that the appearance is due to a homogeneous, structureless, non-cellular exudate which fills the bronchioles and the peribronchiolar tissues and forms as it were a plastering round the inside of the alveoli. It is not fibrinous, like the exudate of crupous pneumonia. Presumably it is an albuminous exudate coagulated in the process of fixation and it is very similar to that which can be seen in fatal cases of poisoning by chlorine gas. French is of the opinion that this albuminous exudate throws much light on the nature of the dreaded cyanosis. If the oxygen in the alveoli has to traverse this albuminous layer in addition to the alveolar wall before it can get to the hemoglobin of the blood, it is evident why there is such marked anoxemia. French states that not one single line of treatment can be credited with saving one of the virulent cases. He thinks that, perhaps, the continuous administration of oxygen might have a good effect. French states his belief that Pfeiffer's bacillus is the cause of influenza proper and subjects the filterable virus theory to severe criticism.

Prevention of Venereal Disease.—A meeting was held at the Mansion House on February 5, 1920, arranged by and under the auspices of the Society for the Prevention of Venereal Disease and presided over by the Lord Mayor of London. The speakers were Lord Willoughby de Broke, president of the society; Sir James Crichton Browne, Sir Arthur Sloggett, Miss Norah March, editor of *National Health;* Professor Sir Ray Lankester, Dr. A. Means Fraser, Portsmouth; Miss Ettie Rout, honorary secretary, New Zealand Volunteer Sisters, and Sir William Arbuthnot Lane, one of the treasurers of the society. The meeting was largely attended and on the platform were many well-known physicians and surgeons. It may be said that the Society for the Prevention of Venereal Disease was founded chiefly, if not wholly, with the objest of advocating by every means possible the adoption among the civilian population of England of early self-disinfection for the prevention of venereal disease. Another body, the National Council for the Prevention of Venereal Disease, has been in existence for some considerable time. The body, however, does not recommend early self-disinfection but relies principally on educative measures. The Society for the Prevention of Venereal Disease, the members of which are convinced of the futility of any method of prevention except that of early self-disinfection, is determined to push vigorously a campaign to legalize this method. According to statistics, early self-disinfection has proved successful among troops and, to a small extent, among a civil population. Miss Morah March and Miss Ettie Rout brought forward at the meeting figures and facts to prove this point. Lord Willoughy de Broke who made the opening speech moved the following resolution: "It is obvious that the best way of avoiding venereal disease is to abstain from promiscuous sexual intercourse. It is, however, certain that a large number of persons continue, in spite of moral teaching, to expose themselves to risk, and so to incur and spread disease among the community, the chief sufferers being women and children. Venereal disease is accountable for a large proportion of cases of insanity, nervous diseases, loss of sight, and sterility. These diseases have become a menace to national health and prosperity, and infection can be prevented by means of self-disinfection, if properly applied, immediately after exposure to risk. It is therefore necessary: (1) To instruct the public as to (a) the vital importance of self-disinfection at the time of exposure to risk as a preventive of venereal disease, and (b) the methods of application. (2) To advocate such further steps for the prevention and ultimate eradication of venereal disease as may be deemed advisable."

Sir James Crichton Browne, who seconded the resolution, sharply criticised the stand taken by the National Council for the Prevention of Venereal Disease and the measures proposed by the council to deal with the situation. He stated emphatically that in his opinion the general public should be informed as to the vital importance of self-disinfection and as to the proper use of disinfectants, so that if they exposed themselves to risks they should know what to ask for and how to use it. The time for plain speaking had come. Scientific truth must no longer be hidden under a bushel. Even now, and notwithstanding the published labors of the Royal Commission, the public did not fully realize the magnitude of the evil or the havoc it was causing.

Sir Ray Lankester defined the aims and intentions of the society forcibly and plainly when he said that to realize its purpose of diminishing and possibly abolishing the awful destruction and maiming of life and health due to venereal disease, the society intended to spread as widely as possible an effective knowledge of the use of disinfectants in arresting venereal disease, and at the same time take steps to insure that it should be a simple and easy matter for anyone to purchase and to keep in a form ready for immediate

use without the delay of any further preparation the two disinfectants approved by authority. The resolution was carried and Sir Arbuthnot Lane moved a vote of thanks to the Lord Mayor for the use of the Mansion House.

A World Congress of Physicians and Surgeons.—As no doubt your readers know, it is proposed to form a World's Congress of Physicians and Surgeons. Dr. F. F. Simpson is now in London with introductions from the chief representatives of medicine and surgery in the United States to consult with the leading men of the medical profession here as to the coordinating and standardizing of all branches of medicine so as to form a World Congress of Physicians and Surgeons, composed of the various international congresses and associations already established. The creation of international associations to deal with specialties which are not already thus provided for is also to be considered. A meeting is to be held this day of writing (February 13), at the House of the Royal Society of Medicine to discuss the matter and it is also hoped to hold conferences on the institution of the Congress in Paris, Brussels, and Rome in the near future.

6. An Unusual Case of Metacarpal Fracture. S. S. Dearborn.

2. Diet Reduction with Retention of Protein to Relieve Glycosuria in Diabetes Mellitus.—R. L. Fenlon describes the method of diet reduction employed in a series of fifteen cases as follows: First step. Eliminate the fats from the diet for one or two days, at the same time maintain the proteins and carbohydrates each at 60 to 100 grams (60 grams protein in the severe cases up to 100 grams in the mild cases). Second step. Leaving the proteins as before, halve the carbohydrates each day until the glycosuria is relieved. (The carbohydrates may be reduced more gradually as indicated by the case.) If the glycosuria still persists when 10 grams of carbohydrate are reached continue at 10 grams for three days unless sugar free before. If glycosuria is still present at the end of three days on 10 grams use step three. Third step. If glycosuria is still present add 50 to 100 grams of oatmeal to the diet for two days. Fourth step. If glycosuria persists, repeat the diet used just preceding the oatmeal days, lowering the proteins one-third. Keep the patient two days on this diet if necessary. Fifth step. If not aglycosuric starve, giving only fat-free broths and water for a two-day period. Sixth step. If necessary revert to the oatmeal diet for two days and again starve. When building up the diet if starvation has been used, build up the protein first to 50 or 60 grams. Then gradually increase the carbohydrates to the danger-point. Lastly add fats, 5 to 10 grams a day in severe cases and 25 grams per day in mild cases. If starvation was not used, the protein is already in the diet. In this case increase the carbohydrates 5-10 grams daily to danger point. Then add in the severe cases five grams every second or third day. In mild cases increase 10 to 15 or more grams daily. When the carbohydrates reach 50 grams, if a break has not occurred before, increase fats as stated above. In the series of fifteen cases there were no deaths, and all were discharged sugar and ketone free.

5. Rupture of the Pectoralis Minor Muscle. William Pearce Coues.

1. Bodily Mechanics and Nutrition.—Lloyd T. Brown, in this paper which was read before the New England Pediatric Society, made the application to the undernourished child of his studies in the mechanical use of the human body. Realizing the differences of opinion and difficulties of judging good or bad human mechanics, three years ago he examined and made tracings of over 700 normal men of the ages of sixteen to twenty-two. These tracings were compared and divided into four groups according to variations found. An examination and comparison of these four groups showed certain points of difference which are perfectly constant. In Group A, which is called good mechanical use of the human body, he found: (1) the head is straight above the chest, hips, and feet; (2) the chest is up and forward; (3) abdomen is in or flat; (4) back—usual curves are not exaggerated. In Group B, called fairly good mechanical use of the body, there are a few slight changes: (1) head is too far forward; (2) chest is not so well up or forward; (3) abdomen shows very little change; (4) back shows very little change. In Group C, which is called bad mechanical use of the body, the changes are more marked: (1) head is forward of the chest; (2) chest is flat; (3) abdomen is relaxed and forward of the chest; (4) back curves are exaggerated. In the last group, D, which is called very bad mechanical use of the body, these four points are exaggerated to the extreme. If the normal is considered the condition found in the average or the great majority of a large group of cases, and if this normal or average is believed to be the correct or best condition, then one is led to think that the Group C position is the normal or best, as 55 per cent. of the 700 men examined belonged to this group. The D group came next with 25 per cent, the B group third with 12.5 per cent., while the A group was fourth and worst with 7.5 per cent. In order to find out which groups gave a story of more trouble or sickness in the past, certain questions were asked concerning the past histories of the men. The results of these questions showed that the operation for appendicitis had been done 1½ times as often in the C and D groups as in the A and B groups; that 2½ times as many men had been operated on two or more times in the C and D groups as in the A and B groups; that three times as many men in the C and D groups showed albuminuria as in the A and B groups; that seven times as many men in the C and D groups as in the A and B groups had bachaches. These figures are suggestive, and, as the writer points out, recall the tracings of men in the A.E.F. who fell down and were unable to stand the strain, which indicate that here, too, the C and D groups, although they are the average or more than average, are not the normal, if by normal is meant as near the perfect as possible. The writer maintains, in closing, that an examination such as was made of the Harvard students and the results of putting the men in the D group to hard work in the war, shows very definitely that this training should begin with young children and that it is the duty of the pediatric and orthopedic branches of the profession to see that it begins there.

1. **An Introduction to the Endocrines in Gynecology.**—Samuel W. Bandler, avoiding the discussion of laboratory tests, studies in metabolism, examination of the blood, vagotonia, or sympathicotonia, confines his consideration of the subject chiefly to the premenstrual and menstrual phenomena, devoting his attention to simple, straightforward, clinical facts. This, with the observation of the patient as a human being (that is, with just a touch of psychology or the study of behavior), plus the element of heredity, completes his scheme of procedure. Endocrine abnormality, he holds, may focus its effect on a definite point or function. An affection of a gland causing either a plus or a minus reaction may therefore evidence itself by totally different symptoms. For instance, diminution of hypophysis activity may result in a typical dystrophia adiposogenitalis. In another patient there may be diabetes insipidus, in another amenorrhea with adiposity. The hypophysis, when hyperactive, may produce acromegaly, dysmenorrhea, metrorrhagia, fibromyomatous growths, fibrosis uteri, an exaggerated metabolism resulting in glycosuria, or the symptoms may be of a general nature associated with excitability or irritability of the type called hysterical. Varying degrees in the intensity of the gland changes, as well as in the location and extent, furnish gradations in symptoms. With a given etiology, several of the endocrine glands may be injuriously affected. These may result in asthenia after labor, after prolonged lactation, after infections, after influenza, and these should be diagnosed as cases of pluriglandular endocrine exhaustion. In other cases one gland may be singled out for marked injury, as, for instance, the adrenals or the thyroid. On the other hand, the test to which any one or more of the glands have been subjected by physiological or pathological conditions may result in an increased secretory activity of one or more members of the chain, as in thyroiditis. The best instance of this is to be found during pregnancy and after labor when many patients give evidence of improved health, bony growth, and general systemic exhilaration. This is merely a continuation of the increased glandular activity aroused in the endocrine chain by the growing ovum. Based on the belief that the ductless glands preside over the development of the inherited body and mind, controlling and regulating many of their functions through all the years of life, the writer offers the following theory of treatment by endocrines. 1. Give those extracts of which the body is producing too little. 2. If the body is producing too much of any one extract, attempt to counteract this overactivity by giving other hormones which diminish, oppose, or inhibit this oversecretion. This, if rationally followed out, calls for a knowledge of the physiological action of the various glands and their probable hormones; one must note the changes produced by overactivity or underactivity of the glands as evidenced by definite physical signs and other signs essential to diagnosis; the gland extracts must be administered in a therapeutic manner, which affords the opportunity of verifying these physiological and pathological facts; and by the results obtained one may prove the correctness or fallacy of either theory or diagnosis.

5. **Blood Pressure in Operative Surgery.**—Albert H. Miller emphasizes the importance, before every surgical operation, of a physical examination, including an estimation of the blood pressure. During operations blood pressure tests provide an invaluable index to surgical shock, hemorrhage and anesthetic overdose. The sphygmomanometer should be used not only in selected cases but as a routine measure. One thus becomes accustomed to normal variations in the blood pressure during operations and is able to detect signs which indicate vital changes in the patient's condition. The Fowler position should not be used after an operation until the circulatory condition has been proved to be satisfactory by blood pressure examinations.

7. **The Eye as a Portal of Infection in Respiratory Diseases.**—Corper and Enright, with a view to corroborating and elaborating the work initiated by Maxcy (*Journal of the American Medical Association*, March 1, 1919), undertook the experiments which are here reported in detail. The experiments were carried out on patients with pulmonary tuberculosis who were capable of expectorating (lung) sputum. They were chosen for the twofold purpose of obtaining satisfactory pulmonary material and with a view to using patients with a respiratory system of reduced protective mechanism such as may occur acutely at any time in any person but not often in a manner available for satisfactory experimental purposes. Suspensions of *B. prodigiosus* were instilled into the eye, after which various parts of the nasopharynx were examined. These results are given in tabular form. It was found that the microorganisms manifested a tendency to follow definite paths. If instilled into the right eye the organisms are found on the right side of the nasopharynx and on the right tonsil, while the left side is free from them, as are also the interior portions of the mouth. Instillations of strong argyrol into the eye were found to follow a similar definite course in the nasopharynx. The direct determination of the presence of microorganisms in the trachea and on the vocal cords, which might indicate a downward passage into the lower respiratory tract after eye instillation, is difficult, and a number of procedures were used by the writers for this purpose. A series of ten cases were examined by passing a metal tube into the trachea from four to six hours after the instillation of *B. prodigiosus* into the eye. The nasopharynx was negative for the organism in these cases for about two hours. It was found that only a small area could be swabbed, but two of the ten cases revealed positive cultures from the vocal cords, one within six hours, the other four hours, after the instillation. In a series of twenty cases the nasopharynx and sputum were examined to determine whether the sputum was positive for *B. prodigiosus* after eye instillation for a longer period of time than was the nasopharynx. The time of the appearance of the last positive cultures from the nasopharynx and pharynx and from the sputum in the twenty cases ranged from one and one-half to two hours in the case of the pharynx, and from one and one-half to two and three-quarters hours in the sputum. From these and the various other findings the writers hold that the eye must be considered as one of the important portals of infection in respiratory diseases, and, although the greater part of the infectious material entering by way of the eye is subsequently swallowed and passes into the gastrointestinal tract, a small but definite portion of it finds its way into the larynx and trachea, where it may persist even as long as a week, as was noted in one case. In its passage from the eyes, the infectious material traverses a definite channel dependent on which eye it has entered or into which it has been introduced. Infectious material that is ingested is far less likely to enter the respiratory tract than that entering by way of the eye or nose.

6. A New Pylorus. G. Gore Gillon.

2. **An Address on the Indications for Cesarean Section.**—H. Beckwith Whitehouse divides the indica-

tions for classical cesarean section into two groups: (a) Cases where a definite obstruction to the passage of the child exists, from disproportion between the fetal and maternal bony parts, malpresentations, or neoplasms, etc. (b) Cases where urgent delivery is called for in the absence of previous dilatation of the birth canal either for the sake of (1) the mother, as in eclampsia; (2) the child, as in placenta previa. The writer performed cesarean section eleven times during the past year, with the following indications: Pelvic contraction: flat pelvis, 2 cases, round pelvis, 5 cases; placenta previa (central), 1 case; eclampsia, 3 cases. The maternal mortality was nil, and there was but one fetal mortality, in one of the eclampsia cases. In this case the infant died on the fifth day, its death, in his opinion, being due to neglect upon the part of the nurse. In four of the cases the cesarean section was performed in the patients' homes and as emergency measures, without any preparation, such as the usual routine before a pre-arranged abdominal section.

5. **The Treatment of Chronic Gonorrheal Rheumatism by Vaccines Given Intravenously.**—Fraser and Duncan were led to employ vaccines in cases of gonorrheal rheumatism as a consequence of having noticed, in cases of this condition in which the patients became victims of influenza during the epidemic last winter, that during and for some time after the influenzal pyrexia there was a marked lessening of the arthritic pains in these patients, and that some freedom of movement in the affected joints resulted. These patients had been bedridden for months, and were showing no response to treatment, in spite of the fact that all the most hopeful lines had been tried on them. These observations recalled the fairly well known fact that in India the more elderly natives submit to plague inoculation not from dread of plague or faith in the vaccine, but because experience has taught them that it eases their rheumatism. Consideration of these facts led the writers to think that a rise of temperature must help the tissues considerably in counteracting germs and their toxins. This is in line with the observations of various other workers. In fifteen cases, four of which are given in detail, the vaccines were given intravenously. A quick reaction marked by a rise in temperature was the result, but there was no marked change in the pulse-rate, nor was there any other untoward symptom. They believe that giving the injections intravenously secures a greater and almost immediate protection. The mechanism would seem to consist of a selective stimulation of the hemopoietic system by non-specific bodies. Probably no single factor is responsible for all the changes that occur, but the intravenous injection upsets the balance of the serum constituents, and the series of changes thus caused establishes a condition favorable to recovery from infection. The vaccines used were not freshly prepared. As a result of storing, probably the toxins contained had broken down more or less. The injection of these, possibly, non-specific germ constituents would seem to have caused the production of specific antibodies. The largest dose of gonococci used was 2000 million. There was no appearance of a clinical negative phase. No benefit seemed to result from an injection that was not followed by pyrexia. At the time the treatment was commenced the patients were extremely debilitated, with a rather fast and weak pulse, which was easily accelerated. There was marked improvement in all cases.

2. **The Importance of the House-Fly as a Carrier of E. Histolytica.**—P. A. Buxton undertook an investigation for the purpose of determining as far as possible the extent to which the house-fly is a carrier of the organisms causing diarrhea, dysentery, and allied conditions. The investigation was carried through in one small area in Amara, Mesopotamia, on the lower Tigris, between Feb. 1 and Nov. 3, 1918. The total number of flies dissected was 1027. The number containing "apparent feces" was 645, or 63 per cent. The number containing human intestinal parasites was 42, or 4.09 per cent. The number containing *E. histolytica* cysts was 3, or 0.3 per cent. The intestinal parasites are the eggs of worms and cysts of protozoa. The "apparent feces" note was recorded if the gut of the fly dissected contained brownish material enough to be seen by the naked eye, and if on being made into a film the brown material agreed in its appearance with human feces. Generally it was swarming with bacteria. The fact, among other findings, that he never found a cyst or egg of any parasite of dog or ox or horse suggests very strongly that the feces found in the fly was human in origin. It was found that apparently the female fly is twice as much a carrier of feces as the male. The detection of cysts of *Entameba histolytica* only three times in over a thousand flies might at first be taken as evidence that the fly under the conditions studied is of minor importance as a carrier of amebic dysentery. On the other hand, it is impossible to remove the whole amount of feces contained in a fly; if a given fly contains but one or two cysts, it is quite possible that these may escape detection. Furthermore, it is by no means easy to see the cysts at all in some films. It may be safely said, then, that 0.3 per cent. by no means represents the number of flies carrying cysts of *E. histolytica;* Buxton thinks the actual percentage 0.5 or possibly higher. This represents a very large number when it is recalled that the fly is found throughout the year in Mesopotamia, and that in spite of the excellent sanitation of most of the units in the area, the fly is abundant in messes and cookhouses every spring and autumn. From his studies Buxton concludes that one may expect to find the egg of any human intestinal worm, or the cyst of any protozoan in the fly if only one looks long enough. It appears that in a well-sanitated area in Lower Mesopotamia over 60 per cent. of the flies carry human feces, over 4 per cent. of them actual human entozoa, and probably at least 0.5 per cent. the cyst of *Entameba histolytica.* One is justified, therefore, in regarding the fly in this country as not only a potential, but an actual and major factor in the carriage of the bowel disorders which are here so regrettably numerous.

4. **On the Direct Cultivation of Tubercle Bacilli from Tissues.**—G. Haswell Wilson describes a method of isolating tubercle bacilli from tuberculous tissues. The method depends on the use of (a) a special medium for culture, and (b) the trituration of the tissue with dry quartz sand before the application of antiformin to destroy contaminating organisms. The procedure is summarized as follows: 1. The disintegration of tuberculous tissue and the destruction of contaminating bacteria by antiformin can be greatly facilitated by a preliminary trituration of the tissue with quartz sand. 2. This procedure appears to exercise no deleterious effect on the bodies of the bacilli or on their vitality. 3. The growth of tubercle bacilli on egg media of the Dorset type is enhanced when the media are prepared with a twenty-one day tryptic digest of horse heart instead of with water. 4. Egg media intended for the growth of tubercle bacilli should be prepared from eggs which are as nearly as possible new-laid. 5. The addition of glycerin to such media inhibits the growth of bovine strains, and the other cultural characteristics of bovine and human strains are well defined.

7. **Obstetric Paralysis—Its Cause and Treatment.**—James Warren Sever states that obstetric paralysis, a paralysis produced during birth, is due to an injury of greater or less extent to the nerves of the brachial plexus. The resultant paralysis is characteristic; the whole arm hangs vertically, the elbow extended, the forearm pronated, and the whole arm inwardly rotated. The paralysis is a flaccid one. By numerous dissections on infantile cadavers the writer has shown, among other things, that traction and forcible separation of the head and shoulder puts the upper cords, the fifth and sixth cervical roots of the brachial plexus, under dangerous tension. This tension is so great that the two upper cords stand out like violin strings. Any sudden force applied with the head bent to the side and the shoulder held would without question injure these cords. Further observation shows that forcible abduction and elevation of the forearm and shoulder put the lower cords of the plexus, the eighth cervical and first thoracic, on a stretch, and when much force is applied it may well lead to a tear, rupture, or other injury to these segments. This condition is seen in breech cases, with arms extended. It may also follow sudden strain when the arm is elevated, such as the so-called hostler's paralysis, caused by the sudden elevation and strain of the arm which occurs when a hostler holds a rearing horse. With the shoulder held and the head carried to one side, with the clavicle intact, considerable force was necessary to injure the plexus. The suprascapular nerve always snapped first, apparently for the reason that it had not so much freedom of play as the others. Even with considerable force the fifth and sixth cervical nerves could not be completely torn across at Erb's point, but frayed out inside the sheath, following a partial tearing or rupture of the sheath, which always gave way first. In some cases there could be produced an evulsion from the spinal cord of the fifth and sixth cervical roots. With the clavicle removed, the whole weight of the shoulder came practically directly on the plexus, and less force had to be exerted to cause an injury. With the clavicle intact there was apparently always enough room, even with the arm elevated and hyperextended forcibly between the clavicle and plexus so that direct pressure from the intact clavicle on the plexus did not seem a possible cause of the paralytic condition. In no case, even with all the force he could apply with his hands, could the writer rupture the joint capsule, or even separate the humeral epiphysis. Neither could he dislocate the head of the humerus. The clavicle can be broken with great force, but fracture of the other bones which go to make up the shoulder joint is practically impossible. Most birth fractures occur in the clavicle, or in the humerus, at about the junction of its upper and middle third. It is not possible to produce a paralysis of the Erb type by the fracture of any bone but the clavicle. In studying Lange's theory, the writer injected the shoulder joints of several infants with methylene blue, and then caused a rupture of the anterior portions of the joint capsule. After several weeks on their backs in the preserving fluid, dissections were made on the infants, and in no case had the methylene blue gone above the clavicle, but completely surrounded and invaded the plexus in the axilla. These observations showed that the exudate from a ruptured capsular ligament of the shoulder does not leave the nerves alone in the immediate proximity of the shoulder joint and seek out Erb's point, the junction of the fifth and sixth cervical segments, at least two or three inches above the clavicle, as others have held. The evident vulnerability of the upper cords of the plexus under any degree of traction made it surprising that the paralysis is not of much more frequent occurrence. *X*-ray studies were made in about two hundred cases of patients ranging in age from two days to eighteen years, and in only two cases had there been fracture, one of the clavicle and one of the upper third of the humerus. Both fractures had healed without incident. The *x*-ray and clinical findings give the classical picture of obstetric paralysis. The cases resolve themselves, with respect to treatment, into two divisions, namely, those to be treated with massage and exercises, principally those of the upper arm type; and those to be treated by operation on the plexus, usually those of the lower arm type. Unless the early treatment has been adequate, the upper arm type will also come to operation, not for plexus repair, but to correct contraction deformities. The writer describes his operation for this purpose. The prognosis in all upper arm type cases is good, provided the case is watched from the start, and treatment properly carried out. In the lower arm type the outlook is not so good, although many of the patients regain use of the upper arm in spite of the persistent paralysis of the lower arm and hand. From this extensive study Sever draws the following summary: Obstetric paralysis is due to stretching or tearing of the cervical roots of the plexus brachialis. It occurs in boys as frequently as in girls. It occurs more often on the right than on the left side. The upper arm type is much more frequent than the lower arm type. It affects both arms very infrequently. It is practically always associated with a difficult labor, in which ether and forceps have been used and force has been applied. Not uncommonly the baby is asphyxiated. Head presentations show the larger percentage of occurrences of both types of cases. It may rarely be associated with fracture of the clavicle but is not the result of a fractured humerus or a dislocated shoulder joint. The prognosis for a useful arm is good in the upper arm type and bad in the lower arm type.

La Presse Médicale.

January 24, 1920, xxxviii, 7.

Unpublished Notes by Laennec on Hepatic Cirrhosis.—Letulle has recently had access to many original and unpublished MSS. by Laennec, some of which relate to cirrhosis of the liver. He was the first to describe the atrophic cirrhosis which goes by his name, but it does not appear that certain chapters devoted to this subject have ever been published. This subject was a favorite of his early days and apparently the pressure of other duties made it necessary to side-track it. Had the "Treatise of Pathological Anatomy" gone through another edition the MSS. in question would possibly have appeared in the chapter dedicated to cirrhoses. The text is descriptive of pathological studies of the most minute and conscientious character. The author isolates mass cirrhoses first. He is not writing of the liver *per se* but of cirrhosis in general with frequent allusions to the liver. It was of course before the days of microscopic control. From mass cirrhosis he passes to cirrhoses *en plaque* and cystic cirrhosis but these two forms receive but ltitle attention. In the mass form he goes extensively into the clinical symptomatology. Much space is devoted to ascites as a concomitant and the symptoms are in part due to cirrhosis and in part to ascites. As a rule the subject with cirrhosis has no appetite and is obstinately constipated. Occasionally we see crises of vomiting and diarrhea which are not prolonged. The author devotes much space to multiform eruptions seen in these subjects, which may possibly belong to *acne cachecticorum* as cirrhosis *per se* is not to-day accused of causing dermatoses. Laennec seems to have found the bile secreted about as usual by these patients and saw but a very few cases of jaundice of any kind. Strange to state there is no reference to alcoholism as a cause. The recurrent febrile and pseudomalarial attacks mentioned by moderns are not cited by Laennec. In an illustrative case the patient had jaundice and ascites when first seen. After tapping, her appetite promptly returned. The ascites, however, recurred as fast as it was relieved and the patient soon succumbed. A thorough autopsy was made beginning with the cranial cavity. The liver did not entirely fill the hypochondrium and its surface was studded with those minute bosses which apparently coincide with the hobnail liver of the English. Laennec does not liken them to any familiar object. The gallbladder contained normal bile. There is no mention of a *caput medusæ*.

"House Burials" in Macedonia.—During the typhus epidemic in Macedonia last year American Red Cross doctors and nurses found that the natives were burying their dead beneath the dirt floors of their homes, in order that the living might retain the food tickets which entitled each person to a certain ration of foodstuffs each day.

Book Reviews.

SHELL-SHOCK and Other Neuropsychiatric Problems Presented in Five Hundred and Eighty-nine Case Histories from the War Literature, 1914-1918. By E. E. SOUTHARD, M.D., Sc.D., Director (1917-1918), U. S. Army Neuropsychiatric Training School (Boston Unit); Late Major, Chemical Warfare Service, U. S. Army; Bullard Professor of Neuropathology, Harvard Medical School; Director, Massachusetts State Psychiatric Institute (of the Massachusetts Commission on Mental Diseases); Late President, American Medico-Psychological Association. With a Bibliography by NORMAN FENTON, S.B., A.M., Sergeant Medical Corps, U. S. Army (Assistant to the Medical Director, Base Hospital 117 A.E.F.); late interne in Psychology, Psychopathic Department, Boston State Hospital; Assistant in Reconstruction, National Committee for Mental Hygiene. And an Introduction by CHARLES K. MILLS, M.D., LL.D., Emeritus Professor of Neurology, University of Pennsylvania. By vote of the Trustees of the Boston State Hospital, Monograph Number Three of the Psychopathic Department. Boston: W. M. Leonard, 1919.

THIS book, the compilation of which was begun in the preparedness atmosphere of the United States Army Neuropsychiatric Training School at Boston, 1917-18, is primarily for physicians, but, as the lamented author states in the preface, some of the material has interest for line-officers, who may see how much "criming" is a matter for medical experts. Of the 982 pages, 903 are devoted to the body of the text and the remaining 79 pages to the very exhaustive bibliography. An index of 21 pages completes the volume. A few illustrations and charts are given.

The subject matter of the work is arranged in five sections, embracing psychoses incidental in the war; shell-shock: nature and causes; shell-shock diagnosis; shell-shock treatment and results; epicrisis. Under the first category are included the syphilitic group (syphilopsychoses); the feeble-minded group (hypophrenoses); the epileptic group (epiletoses) the alcohol-drug-poison group (pharmacopsychoses); the focal brain lesion groups (encephalopsychoses); the symptomatic group (somatopsychoses); the presenile and senile group (geriopsychoses); the manic depressive group (cyclothymoses); the psychoneurotic group (psychoneuroses); and the psychopathic group (psychopathoses).

Throughout the first four sections, which contain the case reports, each subject is introduced by a boxed legend. The last section includes the discussion of terminology, the diagnostic delimitation problem, the nature of war neuroses, diagnostic differentiation problem, general nature of shell-shock, and treatment: general observations. The province of this masterly volume is aptly stated in the introduction: "Dr. Southard's book will prove useful to many workers —to the medical officer whose duty it is to examine decruits for the service or to pass upon and treat them while in service; almost equally to the medical officer in time of peace; to authors of textbooks and treatises and to contributors to neurological and psychiatric journals; to lecturers and clinical demonstrators; to the examiner for the juvenile courts; and to members of the psychopathic, psychiatric, and neurological staffs of our hospitals."

MANUAL OF OBSTETRICS. By EDWARD P. DAVIS, A.M., M.D., F.A.C.S., Professor of Obstetrics in the Jefferson Medical College, Philadelphia. Second edition, revised. Philadelphia and London: W. B. Saunders Company, 1919.

THIS is one of the best known of the smaller books on Obstetrics, and it is not surprising that a new edition is in demand. The present revision includes new matter on the following subjects: Differential diagnosis of early pregnancy; treatment of eclampsia by sedatives; prolapse of pelvic organs complicating pregnancy; chorio-epithelioma; cystic degeneration of the chorion (hydatidiform mole); anesthesia and analgesia in labor; placental bacteremia; inversion of the uterus complicating labor; septic infection at the placental site complicating labor; basiotripsy; and abdominal cesarean section (the Porro operation). To those in search of a concise and authoritative account of modern obstetrics the present volume can be unhesitatingly recommended. The last chapter in the volume deals with "The medicolegal aspect of obstetric practice," and is of more than ordinary value; it contains information for which one looks in vain in many of the larger works on the subject.

FATIGUE STUDY, The Elimination of Humanity's Greatest Unnecessary Waste, a First Step in Motion Study. By FRANK B. GILBRETH, Member American Society of Mechanical Engineers; and LILLIAN M. GILBRETH, Ph.D. Second Edition, Revised. New York: The MacMillan Company. 1919.

DURING the period of the war, which roughly corresponds to the period between the appearance of the first and the second editions of this book, there was notable increase in the recognition of the importance of the elimination of unnecessary fatigue among workers. This recognition arose from the imperative need for the conservation of the strength of the workers, for the increase in production and the elimination of waste, and for the promotion of co-operation. Since the close of the war, these needs have been no less imperative. In this book will be found the definitions and the objects of a fatigue study and the methods by which such studies are best carried out. The results of carefully developed investigations have, as a rule, been most satisfactory, not only to owners but to workmen as well. This work will be both interesting and useful to all of those who have occasion to deal with fatigue conditions.

SANITATION FOR PUBLIC HEALTH NURSES. (The Fundamentals of Public Health). By HIBBERT WINSLOW HILL, M.B., M.D., D.P.H., late Director, Division of Epidemiology, Minnesota State Board of Health, and later Director, Institute of Public Health; M.O.H. of London, Canada; and Professor of Public Health, Western University; now Executive Secretary, Minnesota Public Health Association; Author of "The New Public Health." New York: The Macmillan Company, 1919.

THE purpose of the author of this little volume,—to give to Public Health Nurses a concise view of the fundamentals of modern Public Health as it is to-day, with particular reference to such aspects as may be conveniently listed under Sanitation,—seems to be admirably fulfilled. The sixteen chapters deal with the following questions: Definitions and relationships of hygiene, sanitation and public health; the general course of an infectious disease; typhoid fever as a typical infectious disease, para-typhoid, typhus; more eruptive infectious diseases (scarlet fever, scarlatinoid German measles, measles, small-pox and chicken pox); infectious diseases of the throat, larynx and adjacent areas (diphtheria, tonsillitis, septic sore throat, Vincent's angina, whooping cough, mumps, and colds); poliomyelitis and cerebrospinal meningitis, syphilis and gonorrhea; tuberculosis (human and bovine), leprosy; immunity and anophylaxis; epidemiology; outline of body operation; food; water; milk; flies, mosquitoes, etc.; "cleanliness" and "health"; vital statistics. An index completes the volume.

THE MEDICAL CLINICS OF NORTH AMERICA. New York Number. Volume 3, Number 2. September, 1919. Philadelphia and London: Published Bi-monthly by W. B. Saunders Company.

THIS issue of the Medical Clinics contains thirteen contributions from seven institutions in New York City. They are all of interest and it is perhaps unfair to single out one or two for comment. Dr. Mosenthal's discussion of the Symptoms and Treatment of the Retention of Waste Products in Nephritis is illuminating and instructive and should be of aid to the practitioner in his consideration of these difficult conditions. The author has upset several longstanding traditions and his contribution marks a distinct advance. Rothschild and Wilensky present an article on Cholelithiasis in which they discuss the relation of this condition to the cholesterin content of the blood. It is exceedingly interesting and is likely to prove a valuable aid in directing the treatment of these patients. Other contributions are only slightly less important.

Society Reports.

CLINICAL CONGRESS OF THE AMERICAN COLLEGE OF SURGEONS.

Ninth Annual Meeting, Held in New York City, October 20-24, 1919.

(Special Report to the MEDICAL RECORD.)

First Day—Monday, October 20.

THE PRESIDENT, DR. WILLIAM J. MAYO OF ROCHESTER, MINN., IN THE CHAIR.

Address of Welcome.—Dr. J. BENTLEY SQUIER of New York, chairman of the committee on arrangements, made an address of welcome on behalf of the New York surgeons. He said that three times in as many years New York had arranged to welcome the members of the Clinical Congress of the American College of Surgeons, and twice they had failed, once owing to the necessity of converting the congress into an enormous recruiting station when it seemed more expedient to hold the meeting in a more central place and Chicago was chosen; the second failure was due to the invasion of another enemy, the influenza, and the congress had to be suspended while they fought that scourge. The third attempt was here—none the less hearty because delayed, infinitely more happy because a peace treaty, with or without reservations, had nearly been ratified by a world that at least believed the war was over and that they could devote themselves to subjects of pathological causation and not to the traumatisms of war. During the past three years New York had advanced in the art of welcoming. It had become a habit, a daily civic duty. It was only necessary for the wireless to S O S that a ship was off Sandy Hook bearing important passengers when every New Yorker instinctively put on his silk hat and frock coat and stood ready to rush to the spot designated when City Hall sounded the alarm. The custom of giving the keys of the city with its freedom meant little nowadays. A more gentle tribute to pay a guest was to give him the keys to your wine cellar with your welcome. Then a guest really got something which warmed the cockles of his heart and left a lasting remembrance of good will. To those who were the rulers of the college's destiny Dr. Squier said New York was proud that the first Clinical Congress under the auspices of the American College of Surgeons should have been held within her gates in 1912. New York to-day was speechless in admiration for the work of their secretary general during wartime. His powers of organization, as chairman of the medical board of the Council of National Defense, stood out with the brilliancy of Mars at perihelion. He indeed helped win the war.

Address of the Retiring President.—Dr. JOHN G. CLARK of Philadelphia delivered this address in which he stated that the Clinical Congress of Surgeons of North America had participated in two great events, one the great war and the other the epidemic of influenza. He paid tribute to those who had served and sacrificed themselves in the former and it might be said that doctors and nurses served as valiantly and died as heroically at their posts during the latter as did the heroes of the Argonne. They were now at the entrance of a third event, a new era which they hoped would be the era of renaissance in medicine. Europe had been so weakened and impoverished by the war that it would be at least a decade before she would recover herself and it would take twenty years to restock the ranks of her scientists depleted by the war. The question before us was, "Were we prepared to 'carry on' until Europe had had time to recover?" We did not wish to assume scientific leadership but to continue to advance science while Europe was recovering. Many young physicians came home from the war filled with enthusiasm and many others, inspired by the experiences of the war, were stirred to new ambition. There would soon be a great influx of young medical men from our South American countries. To all these we owed the duty of being prepared to offer opportunities for study that would lead to the master's degree. The wretched post-graduate work of past years should be cast on the scrap heap. In a six weeks or a six months course the student was given merely a smattering and then went into the community to practise medicine. Out of every 100 graduates there was probably only one who had a real creative mental capacity. Men of this type should be segregated and shielded from the necessity of competing for a livelihood by scholarships which would enable them to carry on research work under favorable conditions. The new epoch in medicine should be a renaissance combining the best practical work with the fullest opportunities for research.

Inaugural Address: The Relation of Cancer to the Prolongation of Human Life.—Dr. WILLIAM J. MAYO of Rochester, Minn., delivered this address in which he said, in part, that America was confronted with the problem of reconstruction following war. How she might best meet international competition along with failing immigration and an exodus of temporary residents who were now returning to their European homes with their savings earned in America was the problem. No one among us could be so mean of spirit as to desire the American laborer to return to prewar conditions, but rather did we desire that the laborer and his family should be well housed, well clothed, well fed, and that his children, the future American citizens, should be well educated and equal to grappling with the problems of their time. America must compete in international trade with countries which, devastated by war, contained peoples willing to work long hours for small pay, under labor conditions which we hoped never again to see in this country. Successful competition demanded efficient production. Every person filling an unnecessary position between production and consumption was a double liability; inasmuch as the labor of another was required to maintain him, and what he might produce was lost. This parasitic class was a great source of social unrest in America. Since the close of the Civil War fifteen years had been added to the average length of human life. With present knowledge and present conditions fifteen years more might be added. It was certain that ten years more would be added, at the most productive age from the standpoint of injury. When the speaker was a boy it was difficult for a man of forty to find a new job, and for a man of fifty it was practically impossible. To-day the older men were great assets to the country. If, as a nation, we advanced the time of production for each person ten years, we could well afford to shorten hours of work and improve living conditions, and we should be able to compete with those countries which in long hours and poor living conditions shortened human life, decreased production, and increased social unrest. The introduction of potable water had made prohibition possible. Prohibition would enormously increase production. In Vienna the per capita consumption of spirituous and fermented liquors was reduced 40 per cent. following the introduction of a pure water supply. If one traced the temperance movement through the states of the Union, one found that it was not the appeal to the self control which was behind this great movement, but the advent of potable water.

In discussing the relation of surgery to the prolongation of human life, Dr. Mayo stated that the arch enemy of middle age and beyond was cancer, and our measures both for prevention and cure had not advanced according to the increasing need. One woman in nine and one man in thirteen died of cancer and this proportion of cancer deaths would be maintained in the enormously greater number of persons reaching the cancer age. We must spread more widely the fact that chronic irritation was the cause of the disease. Good dentistry had eliminated a percentage of cancers of the jaw due to the irritation of defective teeth. Cancer of the lip and tongue was on the increase as the habit of smoking was on the increase in both sexes. It seemed to be a well established fact that the incidence of cancer of the breasts was in direct ratio to the amount of covering of the breast and the pressure exerted on it. The influence of drinks too hot to be held comfortably in the mouth in the production of chronic irritation which preceded the development of gastric cancer seemed probable. Unfortunately less

was known about the causes of cancer of the large intestine and rectum. The majority of cancer patients came to operation too late to be cured. The paradox in increased experience in operating accompanied by higher operative mortality and a smaller percentage of cures was seen, and the explanation lay in the increased operability. The surgeon who reported only percentages of operative death rate and of cure, without stating operability, gave us little information. Too little attention had been paid to traumatic transplantation of malignant cells during operation. A considerable percentage of adenocarcinomas of the ovary were due to spontaneous grafting of cells having their origin in cancer of the stomach. These cells were grafted on to the break in the ovarian surface due to the discharge of the ovum, and the secondary infection in the ovary, by rapidity of growth, might mask the primary disease. Other ways in which transplantation of cells might occur were mentioned which showed the need of devising operative methods that would more effectively prevent cell transplantation as well as the traumatic detachment of cancer infected thrombi into vascular channels—a complication which frequently caused postoperative metastatic carcinoma of the liver and lungs. Radium, the *x*-ray, and the radiant energy of heat had a useful field in extending operability, preparing the cancer field for operation, as also after treatment, reducing the percentage of recurrences. Radiotherapy destroyed cells for a certain distance, cells were sterilized at a greater distance so that their reproduction was checked, and connective tissue was caused to develop which acted as a barrier to the further extension of the malignant process. Radiotherapy often failed when malignant cells became attached to the walls of the three-coated blood vessels from which they drew sufficient nourishment to withstand the effect. We had greatly extended the use of radium and had obtained good results in the past three years, especially in inoperable cancer of the large intestine and upper rectum. A colostomy was made as close as possible to the growth and through it radium was introduced directly into the lumen of the carcinomatous area. In the stomach, by means of a Witzel gastrostomy and the introduction of a tube into the cancerous lumen of the area, radium might be directly applied, while the patient was temporarily nourished by means of a jejunostomy. In making suggestions concerning cancer research Dr. Mayo asserted that it was probable that there was a measure of immunity against cancer in all persons and that this was sufficiently great in some to prevent them from having cancer. A search for the cause of such immunity and a means of increasing it was greatly to be desired. The more primitive and important the function of an organ the greater its immunity. The small intestine was primitive and seldom was the seat of new growth; the large intestine had a short heredity and was a frequent seat of neoplasm. The testicle was primitive and was seldom the seat of neoplasm; the ovary was descended from the testicle, had a short heredity, and was the frequent seat of neoplasm. Surgery was striving by all means within its power to reach pathological processes before they became gross. Abstract sciences were being called to their aid, especially physics and biochemistry, in giving a better understanding of physiology and pathology. In this connection the action of colloids was of significance. The biochemists had shown that when certain substances were in the colloid state they were more toxic than when they were in other conditions and this peculiarity had been attributed by some physicists to the energy contained in the colloid body. The physical state of matter might influence those early changes which might result in cancer. The benign cystoid appendix, the escape of its colloidal contents from an aperture in the wall of the appendix into the peritoneal cavity, might result in the grafting of hypoblastic elements upon the peritoneum, with the sequence, pseudomyxomatous peritonitis, myxomatous peritonitis, colloid peritonitis, and eventually cancer. It might be assumed perhaps that the physical activity of colloid particles attacked the tissues and prepared the field for grafting. Again it might change the nature of the disturbed mucous cells in the cystic contents of the appendix and thereby set in motion a series of events which resulted in cancer. The use of energy in the form of rays such as radium, *x*-ray, and heat were examples of biophysics in relation to medicine. These things served to direct attention to the contributions of the abstract sciences to cancer research and to emphasize the need of more intensive study in these new fields.

Gunshot Fracture of the Femur.—Sir ANTHONY BOWLBY of London read this paper, in which he stated that gunshot fracture of the femur occurred in 1½ per cent. of all wounded men. It was one of the most dangerous injuries of war, the danger being proportionate to the extent and nature of the injury of the soft parts even more than to the extent of the bone lesion. An important factor to be considered in estimating the danger of a fracture of the femur was the length of time that was often liable to elapse before the patient could be adequately treated. The early experience of the war taught them that fractures should be splinted as near the front as possible. The treatment of these fractures was considered under two divisions: (1) Treatment at the front, and (2) treatment at general hospitals. At the beginning of the war the splints supplied at the front were very inefficient as well as very few. Within a few months, however, they had been able to obtain supplies of stouter splints made with a metal bracket eight inches long so as to permit access to the wound. These proved very serviceable and were employed for a year and a half at aid posts and field ambulances. The writer described the steps leading up to the adoption of the "Thomas Outfit" and stated that with the use of this outfit the transport of the patient to the casualty clearing station was greatly simplified, for, as soon as the limb was fixed in extension and slung, pain was either altogether prevented or reduced to a minimum, bleeding was soon checked, and the steadying of the fragments effectually prevented further injury to the soft tissues and the spread of sepsis. It was found that the best means of applying traction on the field was by means of steel calipers fixed in the sole of the boot below the instep. The routine treatment of the patient when he arrived at the casualty clearing station was to put him under general anesthesia and thoroughly remove with knife and forceps all damaged tissues and foreign bodies. After operation the Thomas splint was again applied, but this time the extension was fixed to the skin by strapping or glue. In a large number of cases of fracture of the femur primary amputation was absolutely necessary and in such cases should be performed as soon as the condition of the patient permitted. The conditions which commonly necessitated amputation were: complete smashing of an area of bone, extensive comminution of the lower articular end of the femur, laceration of the femoral vessels, extensive destruction of muscles and skin, and gas gangrene. Primary amputation for fracture of the femur was attended with a much higher death rate than was amputation in the thigh for injuries of the leg, and also the higher up the limb was removed the greater the mortality. Primary amputation at the hip was so uniformly fatal that it had been advised not to perform it at all. In discussing the principles of treatment, the writer stated that the apparatus employed should be a skeleton metal splint which permitted traction to be applied either directly downwards or else in various degrees of abduction and flexion. The direction of traction and the amount of flexion and of abduction were guided by frequent radiograms. These were taken by a movable apparatus used at the bed. Without the frequent use of the *x*-ray it was not possible to obtain uniformly good results. The length of the limb was measured daily at first and later less frequently. Even when the fragments were separated by an interval of one or two inches, the gap would be completely filled in by new bone. Fixed extension proved not to be as good as continuous extension. On the whole the use of the patient's body weight was the method most in favor. Movements of the knee-joint were begun early, and slight flexion of the knee was to be preferred to traction on the fully extended limb. For fractures about the upper third and the neck the patient was placed either upon the hammock-like swing cradles invented and described by Major Sinclair or else upon the specially segmented mattress devised by Major Pearson. This latter had been adopted by the Army

Medical Department for use in all cases of fixture of the femur under treatment in England. When union was sufficiently advanced it was the custom to get the patient out of bed while maintaining the length of the limb by the application of "walking caliper splints" fixed to the heel of the boot. Cases treated by delayed primary suture showed a more rapid union of the fracture and a great shortening of the period of pyrexia and were less liable to late necrosis of fragments and to secondary abscess. The question of the removal of bone was not entirely settled when the war ended. There seemed to be no doubt that, on the one hand, the removal of all fragments which might necrose hastened the healing of the wound, while, on the other hand, the removal delayed the union of the fracture and in the opinion of some had been responsible for permanent nonunion in not a few cases. The author quoted statistics showing the results that had been obtained in the treatment of fractures of the femur early in the war and compared with the results obtained in 1918 at the front, at base hospitals, and in special hospitals in England. The final results that were obtained in the limbs that were saved in 1918 showed a great improvement over those of the early part of the war. The majority of cases recovered without shortening; in one series of sixty cases, thirty-six had no shortening, while the remaining had shortening of only 0.2 of an inch; in only 5 per cent. of all cases was there more than one inch shortening. The difficulties of correcting malposition almost disappeared in France as soon as a full length limb could be secured. Eighty per cent. of the cases recovered with good position. In fractures of the shaft it was most important to support the bone at the site of fracture so that the natural anterior curve of the femur was either very fully maintained or even slightly exaggerated. Stiffness of the hip-joint should never occur except in cases where the fracture involved either the neck of the bone or the trochanter. This could always be prevented if care was taken that the foot was not cramped by bandages. Sinuses were seldom met with in the absence of necrosis. It had been the custom recently to remove sequestra earlier than in former years.

Sir Robert Jones of Liverpool said the paper had left very little for him to say, but that he would take the opportunity to express his gratitude for the assistance rendered him by American surgeons. The good results obtained in fractures of the femur in France were also obtained in the cases that came to England. They had obtained an average of only one-quarter of an inch shortening in those cases treated with calipers. In their experience in Liverpool the average shortening was ⅝ of an inch. This carried a very important lesson, namely, that all those cases were treated in the simplest possible fashion with Thomas splints or those similarly made which enabled the patient to be transported in comparative comfort. It must be remembered also that the results secured at the front ought to be secured in civil life with the greatest possible ease without radical operation. None of the cases was subjected to internal splinting. In the early part of the war the men who now treated by internal splinting all lost their limbs. It was not possible to have expert surgery in every hamlet, but it could be made clear to every man that he should treat fractures in the simplest possible way. By treating fractures of the femur as Sir Anthony had described, it was possible not only to get no diminution in the length of the leg, but to get an actual increase. They had learned in the prewar days that weight bearing at too early a period after a fracture of the femur increased shortening, and what was true in the prewar days was true of the compound fractures of war. Hence they made use of caliper splints. These were Thomas splints going to the heel of the boot so that there was no pressure on the leg and the heel did not touch the floor. When these calipers were worn a patient with an ununited fracture could walk with consummate ease, and the patient with a gap in his femur could walk without lameness. This was an important feature in the treatment of soldiers, many of whom had sinuses persisting for months. There were many types of deformity in connection with fractures of the femur, one being a sagging above the knee, and an outgoing of the upper fragment. This sagging required only a bandage. There was no excuse for any deformity in these cases. The deformity resulting from a little overlapping was not as bad as that from a meticulous apposition. In reply to the question, "Do we operate on all cases of deformity of the femur?" the speaker said that if they got good function and good alignment they did not operate if they had even as much as one inch shortening. There was no time when there might not be a recrudescence of infection. There might even be a recrudescence of gas gangrene after twelve months. They did not operate unless they found an erroneous deflection and then they operated in a simple way, doing an osteoplasty. In dealing with postoperative war deformities they found that a stiff knee was often a more difficult proposition than the prewar stiff knee and it did not do so well with passive motion. If one operated on a malunion there was often a greater stiffness than before operation, so that it was essential before attacking bone to decide just what was to be done. If one had a knee with 5° flexion, it was bandaged at 20°. When the patient could lift the limb to 20° it was bandaged at a greater degree of flexion thus gradually increasing the degree of flexion. They had found that it was not advisable to attempt forcible movements, as they might result in rupture of a strand of the quadriceps or stretching of the patellar ligament.

Dr. Fred N. G. Starr of Toronto said he thought that as surgeons they should impress on the public that their service in the war was not an experimental expedition, but for the purpose of giving to the wounded the benefit of their experience gained in a hard school. They were prone to allow the public to rate the surgeon too low, and then there was difficulty when they wanted legislators to do anything for them. He was delighted to hear Sir Robert Jones speak of the Thomas splint. Recently he had had the good fortune to come across the original article of Thomas written in 1875, in which he said it enabled one to handle the patient as though he were a toy, without pain. He had seen that so often that he was thoroughly convinced of the value of the Thomas splint. In fractures of the femur treated by the application of the Thomas splint, frequently when the patient was first allowed up there was lengthening even to an inch. That was different from their prewar experience. One of the benefits of the war experience was the healthy competition between the special hospitals that get some little device that would make for the comfort of the patient or better results in the treatment. All accident ambulances should be equipped with Thomas splints and the men in charge of the ambulances taught how to apply them at the site of the accident. As Dr. Mayo had pointed out, we must consider the welfare of the laboring man.

Dr. Alexander Lambert of New York, President of the American Medical Association, made a brief address of welcome in which he said that the city possessed many opportunities for the study of medicine and surgery which were little realized and it was with genuine pleasure he saw so many here to take advantage of a few of these opportunities, and to enjoy them as they should be enjoyed. They hoped in the near future to draw more and more of the profession here to partake of these advantages. It had been a great pleasure to be present and listen to our friends from abroad.

Second Day, Tuesday, October 21.

Brain Tumor Statistics.—Dr. Harvey Cushing of Boston read this paper. It was impossible, he said, to cover this large field in the short time allotted. However, one could say that in surgery, as in agriculture, it was of advantage to take stock of results of methods employed, to see what developments should be carried further, and what ground should be allowed, as it were, to lie fallow. With this in mind, he had undertaken a statistical study of brain tumor cases (or suspected brain tumor cases) reported during a fifteen-year period. Generally speaking, about 20 per cent. of these were pseudotumors, but 80 per cent. were undoubtedly brain tumors, of which half were verified by operation or autopsy. As the number of verified cases increased, and as one went deeper into the complexity of the subject, it became more and more evident that dogmatic statements belonged to the young and unwise. Statistical presentation was possible but not profitable in a subject in which so many elements were to be consid-

ered. In reviewing such a work as that by Osler and MacCrae on abdominal tumors, one saw that to-day it would be impossible, and to attempt to cover the field of brain surgery in one work would be an unthinkable waste of time. The first point in dealing with statistics was to know what one was talking about. Confusion and ignorance as to what were really brain tumors was undoubtedly less than before. Doubtful cases had to be regarded as pseudotumors, and must be excluded from lists of true tumors. Figures of verified cases had increased; thus from 1890-1900, 11 cases had been observed at Johns Hopkins Hospital; from 1902-12, 337 cases; from 1912-17, 500 cases, and the following year, 1,000 cases. A recent series of 93 cases showed 84 of presumable tumor, 50 of which were certified. Another important question to settle was, which were operative fatalities and which operative recoveries. A case was cited of a young man who suffered from profound attacks of unconsciousness. At operation a large tuberculoma was found. An effort was made to remove it in its entirety. Such operations had an extremely high mortality (in 12 cases of tumors removed, all ended fatally), therefore they were very anxious to have this patient recover. The operation appeared successful. In 3 weeks the patient was up and about feeling well. He was started for Saranac Lake for convalescent treatment. He missed his train and was found wandering about and brought back to the hospital. He then developed tuberculous meningitis and died. Was that an operative fatality? Was that brain tumor or not? Two other cases were cited of patients who entered the hospital within one week of each other. Both suffered from the rarest kind of brain tumor, a cholesteatoma, or mother-of-pearl tumor. From a superficial study of statistics one might suppose this tumor was common, but only 6 had been recorded in the literature. One case was cerebellar and a laminectomy had to be done as well. It was very necessary to establish some standard for "cures." How long must one wait before claiming a cure? In the matter of diagnosis the field of vision was most important. For instance, in the case of a young girl suffering from glioma one could state that there was some pressure uupon the geniculate pathway and not upon the chiasm. This girl was apparently cured by removal of the tumor. It was of the highest importance in these cases to agree upon certain standards of classification so that surgeons might know they were speaking the same language as regards results.

Dr. CHARLES H. FRAZIER of Philadelphia said that Dr. Cushing had made a life study of technical problems and his work was a contribution to American surgery. He would like to refer to the use of callosal puncture in this field. In all pretentorial tumors the symptoms were due to distention of the ventricles which often brought matters to a fatal issue. The increased tension appeared before localization was possible. He had hoped that an opening could be made and drainage instituted in the corpus callosum, and that in an inoperable growth the life of the patient could be prolonged by this means. It was, however, of but transitory benefit. Lately he had combined callosal puncture with subtentorial decompression. His attention had also been attracted by the relation of chronic meningitis to brain tumors. An exploratory operation did not always exclude brain tumor, as the growth might be overlooked. In many cases, however, it seemed that one was dealing with a preexisting meningitis. It was better not to wait to localize a tumor, but to operate early. The use of radium was another point to be mentioned. There was clinical evidence that with the use of radium the tumor underwent retrograde changes. In one such case, that of an enormous cerebellar tumor, so adherent that its removal was impossible, the use of radium was combined with operative measures, and 5 years later there was no sign of recurrence. In another case, where the patient was stuporous and bedridden from a tumor at the cerebellar pontine angle, a tube of radium was imbedded and left for a definite time *in situ*. The patient had recovered so far as to be able to return to work. The speaker's experience with radium had been limited, but it would appear as if this was a distinct clinical aid. As to Dr. Cushing's question in regard to operative mortality, he did not feel that when the patient died of subsequent meningitis it should be charged up to operative mortality. As to the length of cure, this depended on the type of tumor. Endothelial growths were slow-growing. Seven years would not be too long to wait for recurrence. All cases should be under observation at least 5 years.

Dr. ALLEN B. KANAVEL of Chicago said that Dr. Cushing's papers were always landmarks in surgery. Brain surgery stood in particular need of such classifying studies, especially as regarded the point as to how many patients returned to society as self-supporting members. Good results depended not only upon the skill of the operator but upon the opportunity of early and correct diagnosis. The profession was too apt to believe that such symptoms as projectile vomiting, headache, and choked disc were diagnostic. Progress would not begin until medical men learned that these were not the signs of brain tumor, but of its terminal stage. When this was learned, they would be able to cure, not merely relieve, the patients. Symptoms and signs of brain tumor could be classified (1) as due to irritation or depression of the neurological or physiological function of the part involved; (2) as due to irritation or depression of the adjacent parts; (3) as symptoms inherent to the disease, such as the Wassermann reaction, or a high leucocytosis; (4) as the group of terminal symptoms—increased tension, choked disc, headache, projectile vomiting. From the localization standpoint, only the first two groups were important. Too often the case progressed far beyond the stage where successful operation was possible. It was therefore necessary to arouse the interest of the profession to the diagnostic phase of the early stages. A nation-wide study should be inaugurated. Considerable funds would be required for its accomplishment, but it offered a fruitful field for the amelioration of human suffering. Such an enterprise might be established under the auspices of the American College of Surgeons, with the chairmanship of Dr. Cushing. Classified data could be collected and published. This would lend luster to American surgery and undoubtedly give rise to the performance of curative operations, instead of palliative ones.

Dr. CHARLES A. ELSBERG of New York said that anyone who had followed the history of brain surgery during the last 15 years would feel that this field had not received the attention it deserved. The justification for specialization in neurological surgery was well recognized. In a series of 500 cranial operations, 236 were for brain tumors, verified by operation or autopsy; 20 per cent. of these patients died while still under care. The improvement in results in ten years was very striking. The mortality had dropped from 43 to 14 per cent. Last year it was 10 per cent. This was due to combined improvement in diagnosis and technique and more skilful surgical judgment rather than selection of cases. In regard to cholesteatoma, he had seen one case in which three-fourths of one hemisphere was involved in the growth; that is, a tumor as large as a child's skull was found within the skull of a man. The growth was successfully removed and the patient recovered.

Empyema, with Particular Reference to Its Pathogenesis and Treatment.—Dr. ALEXIS V. MOSCHCOWITZ of New York City presented this communication. He said that knowledge of the pathology and pathogenesis of empyema was necessary in order to understand its treatment. His views had been greatly modified by extensive autopsy experience. The view hitherto held was that the pluræ became infected by contiguity with the lung. That did not seem logical, because it did not take place in other serous cavities. It would seem as if contamination must occur from the pleura. In most cases a sub-pleural abscess was found connecting with the empyema cavity. This was the rule rather than the exception, as found at autopsy. A rupture occurred of the subpleural-pulmonary abscess. When the cavity was irrigated with an irritating solution, such as Dakin's, a persistent cough was produced. The analogy between the pleura and the peritoneum was very close, differing only with the greater mobility of the lung, as compared with the sluggish peritoneal peristalsis. The stages were: serous pleurisy was converted into exudate, then encapsulation occurred, which might be either diffuse, localized, or multiple. Seropurulent pleurisy was not encapsulated, but purulent pleurisy was always so. An absolutely free empyema containing

frank pus was an unknown quantity. Frank pus was usually an end-product. The states could be divided into (1) formative, or rupture of abscess; (2) acute, or increase of fluid and toxemia; (3) chronic. The reason why thoracotomy was not permissible in the early stage was that the fluid ran out and atmospheric pressure, at 15 lbs. to the square inch, rushed in, collapsing the lung. This was badly borne by the patient and caused fluttering in the mediastinum with rapid heart action. It pushed out the other lung and disabled the heart. Thus early thoracotomy was attended by terrible mortality. Statistics improved in proportion as the surgeons became frightened by the high mortality. When the stage of adhesions had been reached these formed an anchor for the lung to the side of the chest and then it was safe to operate and evacuate the pus. An acute pyopneumothorax was different. These patients stood early operation. The statistics as to the use of the Carrel-Dakin treatment were rather rosy, but some cases did stay cured. In cases where a pneumothorax had occurred, this tended to disappear. It was safe to sterilize the cavity and close it over a pneumothorax.

Dr. JOHN L. YATES of Milwaukee said that anything foreign to the serous membrane was an irritant—air, blood, plasma, serum, thrombin, fibrin, etc. This irritation, whether due to toxins or to foreign body, provoked an acute serous reaction. Before adhesions formed, the serous fluid had formed and entered the cavities. This was sufficiently irritating to provoke a serofibrinous reaction apart from bacteria, and secondary foci might become more acute than the primary one. The subserosa was extremely resistant, and the best prevention of empyema lay in keeping the pleural serosa in constant apposition. Drainage should be done later. Primary thoracotomy could be done only by maintaining pulmonary inflation.

Dr. JAMES F. MITCHELL of Washington, D. C., said he had been asked, "Just what would you do for empyema?" He thought the answer depended on the type of case. These were of three kinds: (1) acute, (2) chronic, (3) late intractable cases. The profession agreed that early operation was dangerous in streptococcal empyema. It was found that pressure in one side of the chest was not independent of pressure in the other. There was a definite relation between the opening and the amount of air in the lungs. When the lung was restricted by pneumonia the size of opening compatible with life became smaller. Adhesions rendered the opening safer. Attention to diet and early exercise were found to be most important therapeutic aids. The Carrel-Dakin method depended on its intelligent application. Three points might be emphasized: (1) Avoidance of early operation; (2) vigorous application of the Carrel-Dakin method; (3) attention to diet and exercise. Persistent cases should be examined by the *x*-ray method. Stereoscopic plates should be made both with and without bismuth, because the bismuth might obscure a foreign body. The chest wall might be closed regardless of an existing cavity, provided the latter were sterile. The cavity tended to disappear with expansion of the lung. Certain cases would progress to the third stage. *X*-ray studies were then important and the bacterial content should be kept as low as possible. The operation should be as simple as possible. Sloughs should be removed. Small flaps should be used to close the opening. Early exercise should be instituted. There were few cases that would not respond to comparatively simple operations, and the patients so treated would become able-bodied men, without subsequent deformity.

Surgical Treatment of Exophthalmic Goiter.—Dr. GEORGE W. CRILE of Cleveland, Ohio, presented this paper. The conclusions summarized were based upon personal experience of 2,250 thyroidectomies. Fifty per cent. were subjected to ligations. In the last series, 333 cases were first submitted to ligation, then to thyroidectomy. Among 116 ligations one death occurred in the stage of dissolution. Thyroidectomies were done at first without any special precautions, which they had since learned were important. The first 100 cases had a 16 per cent. mortality. With the use of gas and oxygen anesthesia this was reduced to 2.5 per cent. By the adoption of special management of cases, the mortality had been limited to 0.6 per cent. Special operative precautions included: Light anesthesia, gas and oxygen; multiple stage operation; exclusion of the psychic factor. Since the war special precautions had been added against postoperative hyperthyroidism due to excessive chemical activity and destruction by oxidation. With each degree of rise of temperature this chemical activity was increased 10 per cent. With a temperature of 106°, metabolism was increased 70 per cent. Another point of importance was the discovery by the British Research Department that the wound could be left open under a dressing of 1:5000 flavine. This permitted the surgeon to stop at any point at which he found the patient was not enduring the operation well. Lobectomy was performed under analgesia, as the inhalation anesthesia interfered with internal respiration in a patient already suffering from suboxidation. Hypersensitiveness was sufficient to destroy the patient. Complete team work was essential to success in handling these patients. It could be said that the operation was performed by the hospital and not by the surgeon. The differential diagnosis was greatly aided by the Goetsch adrenalin test and basal metabolism determinations. The psychic control of the patient was of the highest importance, as was the preoperative and postoperative care. When there was an excessive postoperative temperature the patient was put in an ice pack. In view of the striking results obtained no case was rejected on account of its gravity.

Dr. DEAN LEWIS of Chicago said that two types of goiter had something in common. Those cases marked by tachycardia without exophthalmos did not differ from ordinary thyreotoxic goiter. The cases of hyperplasia of the thyroid epithelium presented the classical four signs of exophthalmic goiter. Surgeons were apt to want to operate too soon, but these cases had to be nursed along and the exercise of judgment made all the difference between one surgeon's success and another's. The speaker said he did not know what postoperative hyperthyroidism was; he did not think any other surgeon did. He thought Dr. Crile was inclined to attribute too much credit to his staff and too little to his own skill as an operator.

Dr. CHARLES H. MAYO said he felt considerable diffidence in following this galaxy of stars. They did not all agree, yet they often arrived at the same results. He felt that the people of this country had a claim to a birthright of good health, which they might lose through ignorance. A control of the situation would bring the people into their just rights. In regard to goiter, the Surgeon General's report showed that 15 per 1,000 was the rate in the Northern Pacific States. There was almost none in New Hampshire and Vermont. There were perhaps more mistakes in diagnosing exophthalmic goiter than in any other condition. The thyroid was not essential to life, but it was synonymous with making life worth living. The cell changes in the thyroid were due to increases of biochemical products by bacteria coming from different parts of the body and acting on the thyroid. Two-thirds of the cases were simple hyperplastic glands. A second type was caused by areas of degeneration throughout the gland. A hyperplastic gland sometimes went with myxedema—a sort of burned-out condition. Thyroid substance working with adrenin controlled the cell metabolism. In hyperthyroidism there was a burning of fats, a rapid oxidation, and these people literally destroyed their own cells. The thyroid gland bore relation to the elimination of nitrogen. Retention of nitrogen led to tetany. Creatin and creatinin had almost the same chemical constitution as the thyroid secretion. There was, however, no positive determining factor to tell what was the controlling influence in thyroid action.

Third Day—Wednesday, October 22.

Stiff and Flail Joints.—Sir ROBERT JONES of Liverpool delivered this address, in which he stated that one of the common products of the results of war injuries was the flail joint. The greater number of these disabilities were the direct results of excisions deliberately performed at casual clearing stations or base hospitals. They were performed in order to save the limb from amputation or the patient from death, by minimizing local sepsis and preventing general sepsis. Cases of so-called limited section had resulted in better function than was obtained in those in which the excision had been extensive. Moreover, cases in which

sepsis had been overcome and bones allowed to remain in position had resulted sometimes in a very good firm ankylosis with excellent function if the position of election had been maintained. There was no reason why any joint should be allowed to heal at functional disadvantage. A flail joint might follow as the direct result of excision following the removal by the surgeon of large comminuted pieces of bone, the direct loss of bone from missiles, and the extrusion of necrosed bone during sepsis. The extension applied should be very moderate and of short duration. In the treatment, ankylosis should be aimed at rather than mobility. In limiting the extent of excision muscular attachments should be preserved. The fact that they aimed at ankylosis did not mean that they attained it, but the effort left the best possible results for reconstruction. The rule should be that, as soon as the surgeon could do so, he should place the bones as nearly together as he could and in the best position for future functioning, whether a pseudoarthrosis or an ankylosis occurred. The author described in detail typical procedures to be employed in the treatment of various joints. He considered bone grafting as generally understood of very limited application in injuries of the upper part of the shaft of the femur. Ankylosis in the case of limited excision of the hip was of no advantage and certainly did not justify the severe operation which it would necessarily entail. The only practical cure of a flail knee was ankylosis and if the bones were in good position nothing was needed but to saw the ends and fix them with screw or nail. Where there was a wide separation associated with sinuses it was necessary, after sawing the ends of the bone, to bring a bulky sliding graft from the tibia or femur and wedge it in at right angles to the line of the joint. A flail ankle was so rare that he could not recall an instance of it as a result of a war wound. Many operations for fixing the shoulder had failed because the surgeon had been content to bare the glenoid and freshen the humerus. This was quite insufficient. It was extremely important before the arm was ankylosed to ascertain whether the scapula was mobile and whether it retained its normal position in regard to the humerus. If the scapula was fixed and the arm abducted the result was a tragedy, for the patient would have a fixed abducted shoulder with an arm that he could not lower. In the elbow, if the bones were pointed and distant, nonoperative treatment could not be successful even with good muscular control. Operation must be designed whereby large apposition of raw bone surfaces was secured. The principle for operation was to freshen the bone ends, split them without detaching the fragments, enlarge the area of bone apposition, and firmly immobilize. The attempt should never be made to stabilize a flail joint and permit of voluntary movement unless there was sound muscular control. War had taught us to discard methods of force in favor of persuasive and gentle methods. In closing, he paid a tribute to the young surgeon who had left an indelible impression upon the evolution of surgery. He felt that these younger men should be given more liberty of action, that the older surgeon should make more use of them, and that they should be given larger opportunities to be useful. It was a tragedy to see men of thirty or forty years of age forced to content themselves with the crumbs that fell from the table of Dives. They should be offered the hand of friendship even when they criticised and sought to improve upon our methods.

Dr. JOSEPH A. BLAKE of New York expressed his deep appreciation of the masterly presentation of this subject upon which there was no one better informed than Sir Robert Jones. He also voiced the gratitude of American surgeons for the assistance so generously extended them by the British surgeons which had resulted in saving the lives of many American soldiers. He had nothing in the way of criticism or addition to the subject presented. In his opinion the question of stiff and flail joints should be considered, first, from the standpoint of prevention and, second, from the standpoint of treatment. If the treatment of the articulations was properly carried out a stiff joint rarely occurred unless there was disease, and consequently the preventive treatment was extremely important. If one wished to conserve the motion of a joint he should never allow it to be lost. This meant motion from the time of the injury, not several times a day, but by an arrangement whereby unconscious movement might be made at any time. It was desirable that the patient should make the motions himself, since active motion not only maintained the functions of the muscles but made new bone conform to the architecture of the joint. Not only did active motion prevent deformity, but it favored healing by improving the nourishment of the parts. The reconstruction of muscles was possible only in the hands of a man who understood the technique thoroughly and also understood the after-treatment. It had been impossible to make this treatment general because there were not the men to carry it out. In a joint already stiffened one was confronted with the alternative of permanent ankylosis or a return to motion by proper treatment. In the first class, one must consider whether motion was more valuable than a possible loss of stability. He had great faith in active motion by the patient himself under proper instruction and guidance, but active motion should never be carried out to the point of traumatism. The practice of breaking up a stiff joint under an anesthetic was utterly and absolutely reprehensible and should never be done. Traumatism thus inflicted not only caused suffering but, worse, necessitated repair, and consequently additional ankylosis. It was surprising how little force disrupted a bone in which rarefaction had taken place as the result of disuse.

Dr. JOHN L. PORTER of Chicago said he was very glad to hear the frequent use of the word ankylosis in the presentation this evening. In his work at Base Hospital 46 he had dealt with a number of cases of flail shoulder and flail elbows, cases in which the articular ends of the bones had been shot away, the wounds had become infected, and scar tissue had formed in the gaps. They had devised a special wire splint for the treatment of these cases, because it was evident that flail joints were produced by the action of gravity in a joint in which the bones were not sufficiently well approximated. With this splint they had been able to hold the bones at the shoulder and elbow together and to secure sufficient fixation, though not ankylosis, to make the joint useful. When healing was complete active and passive motion was instituted. A flail shoulder was caused by the fact that the humerus had lost its fulcrum, and a flail elbow by the fact that the ulna had lost its fulcrum. There were numerous devices for splinting that would supply a fulcrum for flail elbows. While they were justified in trying to secure some mobility in the upper extremity, the chief consideration was stability. Since stiff joints were of as much interest as flail joints and much more frequent, he wished to say a word about them. During the last decade various operations had been devised, known as arthroplasties, all of which had as their object the keeping of denuded joint surfaces apart and permitting motion. In the beginning they interposed autogenous flaps of fat and all sorts of tissues that would permit of motion. It seemed that they were in danger of losing sight of the fact that stability must be preserved if the joint was to be useful. The results of such operations on the knee-joint were as a rule disappointing as they left the patient with neither a flail nor a stable joint, and often with 35 degrees of motion instead of 90 degrees. With such a knee a man could not go up and down stairs. He felt that he would rather have a stiff knee fixed at an angle of 10 degrees than an unstable joint. A stiff shoulder was very disabling if it was fixed close to the body, but if the arm was in the position of election, a slight abduction, one could get along quite comfortably. In reply to the question as to whether they had accomplished anything worth while, it might be said that they had learned that more stiff joints could be mobilized than formerly because they had seen some good results. They had already seen very excellent results in the smaller, non-weight-bearing joints. They had learned that they should not transplant an inelastic tissue on to a synovial surface. They had learned that supposedly absorbable substances did not absorb and that a foreign body introduced into a joint was always a foreign body and interfered with mobility. If they were going to get anywhere their mechanical shortcomings and surgical enthusiasm must

be counterbalanced by a fair amount of common sense.

Dr. JOEL GOLDTHWAIT of Boston, in offering tribute to the British delegates, said that the fact that in our army there were only 4,000 cases of amputation was due to the established methods of handling the wounded taken largely from England, for which Sir Anthony Bowlby was responsible. Then in the treatment after the first line work we had followed almost absolutely the methods laid down by Sir Robert Jones. In May, 1917, when the request came for 20 orthopedic surgeons to assist Sir Robert Jones, these were sent and others followed, until we had nearly 100 men being gradually trained in correct methods of orthopedic surgery who were ready for our service when we needed them. These men had been trained in the preservation of function, and as a result over 400 young surgeons had come back to this country trained as nothing else could have trained them. A flail joint was something one rarely saw in civil life, but stiff joints were quite common. There had been a decrease in the number of operations on stiff joints. It was a simple matter to mobilize a stiff joint, but the procedure should be designed with the idea of getting as useful a limb as possible. The shoulder in the proper position was much better stiff than flail. A flail elbow was better than a stiff joint. The knee-joint should never be mobilized when once it was completely ankylosed. The hip-joint was fairly easy to mobilize, and many times the patient was better off if this joint was mobile. Fingers were very easy to mobilize. The question to be taken into consideration in deciding whether to mobilize a joint was whether it was going to put the patient in a position where he would be able to earn his livelihood.

Sir ANTHONY BOWLBY said that the first time they had come into contact with the American surgeons was when the British had urgently requested their help. That was at the time when they had decided that many more operations should be done at the front and the question was to find surgeons to do them. Their casualty clearing stations had but six surgeons per thousand men, whereas the Americans provided seven surgeons. At that time the British were working with an average of two and a half surgeons per thousand men. It was only by changing the men from one part of the front to another that they had been able to keep pace with the wounded. The wounded during the battle of Paschendale numbered 196,000 and during that fight they had under anesthesia 60,500 wounded soldiers. At a later period they operated on a corresponding scale, caring for 311,000 wounded men during three months. The number of limbs and lives saved by early splinting could not be exaggerated.

The Physician and Surgeon in the Industrial Era.—Dr. OTTO P. GRIER of Cincinnati read this paper. In introducing his subject, he said that two outstanding problems presented themselves for solution. First, how might permanent international peace be secured, and, second, how might national peace be brought about? Permanent international peace could not come unless there was peace among those who made up this nation. We could not have permanent peace within the nation if the majority of people were badly or unjustly dealt with, and were suffering want, for this interfered with production and the government became unstable. This was not only an industrial era but an era of the greatest industrial strife. Labor was organized. This was the day of group actions and the medical profession must readjust itself in accordance with the group idea. Was it right that the physician who had a close view of the living and thinking of the people should play so small a part in their lives? Were they doing all they could to bring about the health and sanity that were basic at all times to the national welfare? It had occurred to labor to seek compensation for loss of time and wages through illness ahead of the medical and surgical professions, with the result that workmen's compensation laws and group insurance schemes were being promoted without seeking the guidance of those best fitted to inspire and direct such undertakings. As a consequence of neglect to take cognizance of these things on the part of the leaders of the profession they had the general practitioner tinkering with industrial injuries with the result that disability was prolonged and there was a greater loss of time and wages to the workman, a loss in time and money to the employer, and to society a greater burden. Was it not the surgeon's responsibility to get the injured man under the care of the best trained surgeons in the profession? To their failure to keep abreast of the times in these matters might be attributed in a large measure the fact that in President Wilson's Industrial Conference the medical and surgical profession had no representatives. If the profession did not awaken from its social or rather unsocial, torpor legislation would be passed to please labor or capital but would have no consideration for the interests of the profession. Did these facts suggest why they had not been successful in their demand for a Federal Department of Health? The autocratic employer of yesterday was more than matched by the employee of to-day. Was the medical profession not the latent force which if properly applied would do much to lessen the strife and narrow the gulf between capital and labor by humanizing industry? If there was such an opportunity for human service should they not fit themselves to meet it? Their usefulness in the discussion of social problems had not thus far been noteworthy. However, during the past decade there had been developed in response to the demand of industry the industrial physician who was desperately trying to cope with the industrial problems and the surgical problems which were quite different from the problems the physician met ordinarily. He must be familiar with all the factors which affected the health of the employee, with the sanitation of the factory and the workingman's home, his food and his habits, with occupational diseases, with the effects of fatigue and long working hours, and he must know to what extent the laborer's soreness of mind was the result of long hours and the monotony of his work. The medical profession must square itself with the new social era. To enable it to do this provision should be made for the special training of physicians and surgeons through the establishment of university departments, post-graduate courses, and endowed research institutes. The industrial physician must be attentive to the rising standards of medicine, for he was the moulder of opinion in behalf of preventive medicine.

Dr. JOHN J. MOOREHEAD of New York said the facts and figures given by the previous speaker emphasized the medical and surgical problems incident to industry in these after-the-war days. War was and always had been a waste in things human and material. The human salvage organization represented by the medical corps of our army did an enormous work during our period of conflict, a work in which the membership of this congress was well and creditably represented abroad and at home. Those of them who had been in the war had learned in a hard school to centralize their efforts and to appreciate the effect of directed effort, of effort focused upon one problem, and that problem was human salvage. And now, a year after the actual conflict had ended, a new problem awaited us, another salvage problem, the reclaiming of those laid low by industrial warfare. Our attention even before the war was being directed to this problem, we were awakening to the necessity for better care of the injured, to the prevention and cure of occupational disease, to the many phases of sanitation in the workshop and more especially in the homes. It needed no argument to convince us that thus far only desultory attention had been given to the care of the injured, to those problems of traumatic surgery which caused so much disability, which produced often a state of crippling that was a reproach to modern surgery. With a profession aroused to a high pitch of enthusiasm by their success in caring for the war wounded was it too much to expect that the surgical and medical lessons of the war could be carried to an equal grade of care for those injured in peace times? The problem was largely one of education, of direction given primarily in the medical college, transmitted by the visiting staff to the hospital interne, made the subject of clinical demonstration at surgical meetings. Several of the colleges had already inaugurated special courses in these branches—Johns Hopkins, Harvard, University of Michigan, Cincinnati University, and others. In this city Columbia University was undertaking a similar project. The medical student of the future was sure

to be better posted than those of the past generation in the care of the injured. The time had gone by when a visiting surgeon could delegate the care of the fractures in his service to his junior, who in turn passed them to the house surgeon, who in turn passed them to his junior. We should recognize that traumatic surgery was, in the mass, major surgery, not minor surgery; that the care of an infected hand or a fractured ankle required at least as much surgical skill and judgment as the care of an internal appendix or a hernia. We should take advantage of the great mass of information at our disposal respecting the after-care of the injured, the newer methods for shortening disability, for preventing deformity, for reducing the numbers of the crippled. We should realize that this was a problem on the road to becoming a specialty, one demanding a training and experience that made of its possessor a teacher, a leader. The other problems of pathological surgery had been mastered by a similar concentration of effort; this problem would yield to a similar process. One concrete suggestion offered was that this congress establish a counterpart of the Inter-allied Surgical Conference, that great group of surgical and medical minds that met in Paris every two months and standardized the proved methods of treatment based on enormous experience. Their expressions of opinion became virtually an authoritative textbook. When they had a bureau of standards of this sort, made up from the membership of this congress, they would have placed this problem in an advanced position, and would have a consensus of opinion the best obtainable, they would have made a real progress, and would have solved one of the most important problems now confronting a reunited profession intent on carrying that spirit of service displayed in war into this after-the-war period. Educational leadership was all that was needed to make of this duty an accomplishment; of this opportunity, an acceptance; of this reproach, a credit; of this menace, a success; of the cripple, a restoration. Preventive medicine had no greater goal, surgery no better prospect.

Dr. William O'Neill Sherman of Pittsburgh said it was only within the last decade that mechanics, chemistry, and engineering had made it imperative that medical men readjust themselves. The psychological time had arrived for scientific medicine and surgery to take its place in industry. The human factor was the greatest asset in industry if properly conserved and directed. There were at least 500,000 industrial accidents in the United States annually and 90 per cent. of employees needed medical or surgical care in the course of the year. The vast majority of the injuries were minor wounds that might easily be converted into serious wounds if not intelligently cared for. Industrial accidents were responsible for the loss of many millions of dollars yearly. This frightful loss could be greatly diminished by applying military surgery to industry. The problems of military and industrial surgery were similar. The average practitioner was ignorant so far as training for military service was concerned and the same was true in regard to his training for industrial surgery and industrial hygiene. Men trained for this work might be secured through the establishment of courses of military and industrial surgery, medicine, and hygiene in all medical colleges, and by endowed research institutions in industrial surgery and hygiene with provision for postgraduate work in these branches. Harvard had established the first school in industrial medicine and surgery.

Dr. Jonathan M. Wainwright of Scranton, Pa., said it did not matter just how large or small the casualty list was; it was large enough to demand the most careful attention. Much might be done in the way of reconstruction. Here all the methods of physiotherapy were applied. If the question were asked as to which was more important the dispensary or the operating room, he would say the dispensary, for it served more patients than the wards of the hospital or the operating room, yet the consultant seldom went into the dispensary. He spent his morning in the operating room and when he had finished the major operations said, "That is all except a few minor cases which the house surgeon will attend to." Perhaps among these minor cases was one of a palmar abscess, and this required more care and judgment in making the incision than an appendectomy. Perhaps the man with the palmar abscess was an engineer, a useful man with his life before him, and it was more important that he be properly treated than that the old lady with a cancer of the breast who was already a burden to herself and society should be properly cared for. The hospital should offer the greatest good to the greatest number; the dispensary was economically and industrially more important than the hospital and should be provided with the best trained talent. We should ask ourselves whether the thousands of injured people were getting all they deserved. Was the community doing what it should do? Were adequately equipped physiotherapy departments available? Was surgical care available for the patient who could not afford it? Did this representative body owe anything in this connection to the community which it represented?

Mr. R. M. Little of the Safety Institute of America, New York, spoke from the point of view of American industry. He claimed that 700,000 industrial workers in the United States lost more than four weeks' time as the result of accidents annually. There were at least 22,500 industrial deaths annually, and our industries turned out each year at least 15,000 workmen suffering from permanent disability. The loss of nine days annually by each of 50,000,000 laborers on account of sickness (the estimate of the United States Department of Labor) meant a tremendous industrial and economic loss that ought to be brought to the attention of the American College of Surgeons. Industry was responsible for the stability, wealth, credit, and resources of the nation. It was imperative that the knowledge of the surgeon be brought to bear practically upon the problem of the tremendous national loss due to sickness and disability among those engaged in industry for the welfare both of the country and of the world. Every medical school must have soon in operation a chair of industrial medicine and surgery, so that medical students could be trained for this industrial service. If the physician and surgeon were to succeed they must have the industrial point of view. The Museum of Safety had improved conditions and had made excellent progress. Accidents, through their efforts, had been reduced in some plants as much as 80 to 90 per cent. It was perfectly possible for the surgeon to accomplish as great results if he found a way to apply his skill. The physician had always waited for the patient to come to him. Let him carry the message to Garcia. He must go into industry and there have well equipped clinics and hospitals as good as the profession could devise. There was a paramount need in industry for well trained medical and surgical officers. He admired the ethical ideals of the profession, but what it was not possible for them to do individually, could they not do collectively? They could correspond from the office of a secretary with the large industries, chambers of commerce, merchants' associations, and trade bodies, and could convince them of what medicine and surgery could do if its knowledge were applied to the solution of industrial problems. The reduction of accidents and the loss of time through sickness were necessary for a full productive life. At present the country was not producing within 50 per cent. of what it should be producing and for this reason as well as for many others this organization should lend its help.

The Standardization of Hospitals.—Dr. John G. Bowman of Chicago, chairman of the Committee on Hospital Standardization, outlined the following minimum standard which the American College of Surgeons asked hospitals to put into effect: "(1) That membership upon the staff be restricted to physicians and surgeons who are (*a*) competent in their respective fields, and (*b*) worthy in character and matters of professional ethics. (2) That the staff hold meetings at least once each month to review and analyze the successes and failures in the treatment of patients. (3) That accurate and complete case records be written for all patients and filed in an accurate manner in the hospital. (4) That clinical laboratory facilities be available for study, diagnosis, and treatment of patients." Such a standard would not only assure proper care and treatment of patients but would put the board of trustees of hospitals in possession of essential information which many such boards did not now receive. Among the 617 general hospitals of more than 100 beds in the

United States and Canada, about 478 could not now present even a fairly complete analysis of their clinical work. It was urged that communities withhold their support, financial and otherwise, from hospitals whose trustees could not inform the community as to the character of treatment received by their patients, such as would be provided by the college's minimum standard. Matters of incompetence should be dealt with in no uncertain manner. The doctor scarcely existed who, if incompetent and his incompetence was brought to his notice at frequent intervals, would not either endeavor promptly to perfect his training or retire from membership on the staff. The same principle was true regarding character and professional ethics.

The Acute Abdomen.—Dr. JOHN B. DEAVER of Philadelphia read this paper, in which he declared that the fact that the acute abdomen was a condition calling for careful judgment and thoughtful consideration was obvious; that it occupied too prominent a place in mortality statistics was unfortunately all too true. It must be admitted that among the reasons for this was the fact that too many untimely and unsuitable operations were performed in the treatment of this serious condition. This was in part due to the want of intimate knowledge of living surgical pathology, in part to too great a reliance on laboratory findings which did not always correspond to the findings at autopsy and *in vivo*, and to the hesitancy to resort to radical measures in the hope that the symptoms might pass away under what was called conservative treatment. The acute abdomen was not, as a rule, the result of virgin pathology. In the majority of cases it was the outcome of a chronic pathological process which had existed for a well marked period of time, and to conditions that should have pointed the way to surgical treatment. Occasionally the acute abdomen resulted from conditions not recognized by even the most astute. These included mesenteric thrombosis; acute obstruction due to intestinal strangulation by an unusual formation, such as a diverticulum; obstruction in an internal fossa, or to hernia through a congenital hole in the mesentery or in the diaphragm. The reduction by taxis of an irreducible hernia should be relegated to the practice of the middle ages. The more common causes of the acute abdomen such as chronic appendicitis, typhoid perforation, chronic salpingitis, ovarian cyst twisted on its pedicle, chronic intestinal obstruction, pelvic lesions, or hernia of long standing, should be recognized if the patient were carefully studied. The foolish belief that chronic ulcer, chronic gallbladder disease, chronic pancreatitis, etc., could be cured by medicine, diet, rest, etc., was a perverted faith that courted disaster. The acute abdominal conditions following surgical procedures were intestinal obstruction, secondary abscess, and peritonitis. After discussing each of these conditions and the difficulty of diagnosing the traumatic acute abdomen, Dr. Deaver said that every abdominal wall which showed a penetrating wound, whatever its location and whatever the agent that inflicted the wound, should be opened. Similarly, severe blows on the abdomen, or a fall on the abdomen, or a crushing between wheels or between cars, should bring to mind the possibility of one of the various subacute injuries that not infrequently occurred. In these cases it was better to open the abdomen on suspicion and find nothing there than to wait for an assured diagnosis and hemorrhage. The earlier the acute abdomen was seen the more confident could one be of the diagnosis, and the earlier suitable treatment was instituted the more favorable would be the prognosis. Of course, suitable treatment meant surgery. There were certain conditions of the abdomen in which surgery was not indicated and it was these that he placed among the "untimely" operations which swelled the mortality lists. Prominent among them were acute dilatation of the stomach, acute postoperative gastric dilatation, acute gastroenteritis simulating appendicitis, conditions operated on too often with fatal results. A more frequent mistake was that of regarding an acute appendicitis with peritoneal irritation as enteritis and deferring operation until too late. Pneumonia and diaphragmatic pleurisy, causing upper abdominal rigidity, had been mistaken for the acute abdomen; operation, and especially anesthesia, was unfavorable in such cases. The gastric crises of tabes had been mistaken for the acute abdomen. The doctor and the laity should know the harmful possibilities of the purgative. The danger of giving morphine before arriving at a diagnosis was, he believed, well understood, and the purge belonged in the same class, but was more deadly than morphine. In obstructive conditions there was never anything gained by delay. In the acute abdomen that was amenable to surgery, early intervention was of course the best procedure. On general principles it might be said that in the presence of the acute abdomen with diffuse peritonitis, in the absence of a reliable history or a reasonably sure diagnosis and of a localized point, it was the part of good judgment to defer operation, treating the patient by strict anatomical and physiological rest. In circumscribed or localized peritonitis, with definite knowledge of the point of origin of the peritoneal inflammation, operation was comparatively, if not entirely safe, with proper technique. The dependable factors for determining for or against operation in this condition were: (1) experience, (2) interpretation of a carefully elicited history, and (3) careful examination. The carefully elicited history was the point around which diagnosis would develop. He did not attach the same importance to the blood count that some surgeons did. In this hackneyed subject much that was important had not been thoroughly standardized. Here was a field of research quite as important and profitable as much that he observed less worthily bearing the name of research.

Dr. J. M. T. FINNEY of Baltimore said that Dr. Deaver had forgotten one important thing and that was that all surgeons were not John Deavers. There were two important things to be borne in mind, one was the diagnosis and the other the treatment. The main question was how to get the diagnosis. He cited several cases in which the symptoms pointed to an acute abdominal condition and the patient was found in the course of twenty-four hours to have measles. These cases served to emphasize the danger of mistaking something else for an abdominal crisis.

Dr. GEORGE E. ARMSTRONG of Montreal spoke of the acute traumatic abdomen and cited cases illustrating the difficulties in diagnosis referred to by the previous speakers. After certain traumatic injuries to the abdomen there was a quiescent period of from twelve to twenty-four hours for the surgeon and the patient to decide what was to be done. In two cases coming under his observation after traumatic injuries, the small intestine had been completely severed and the local reflexes had closed off the ends of the intestine and prevented leakage. The symptoms in these cases were not alarming and the question was what to do. When the acute abdomen was well developed the diagnosis was easy. The symptoms that justified the surgeon in opening the abdomen were: (1) a history of injury of a character that might have caught the intestine between the impinging object and the vertebræ; (2) if that injury was followed by practically complete disability, in the sense of complete disability following the fracture of a limb; (3) if the patient lay in bed practically helpless; (4) if associated with that history and disability there was abdominal tenderness. Under such conditions one might advise opening the abdomen, and, if the circumstances were favorable, as soon as possible. The speaker emphasized the evil of purgatives and said one could easily see their disastrous effect in cases such as those mentioned in which the intestine had been divided and the ends closed by reflex action of the nerves. He also emphasized the inadvisability of giving morphine and stated that rest and application of ice would relieve the suffering. Morphine would relax the local reflexes, and might permit of dangerous leakage. There were cases in which it was well to have the courage to keep cool and to wait when the symptoms were few.

Dr. STUART MCGUIRE of Richmond, Va., said he had tried to find something in the paper to criticise but he approved of everything that Dr. Deaver had written. He thought, however, that some of the principles enunciated needed elaboration or surgeons who did not have Dr. Deaver's skill might perform operations which Dr. Deaver would not approve of in practice. It was necessary to make clear that the acute abdomen was not always surgical and that sometimes when it was surgical it had reached the stage in the

disease when operation would be unwise. The statistics of Dr. Cabot and of others showed the large number of mistaken diagnoses and many unnecessary operations. Such unnecessary operations had been performed in typhoid fever, acidosis, pyelitis, measles, and other diseases. Lead colic had been operated on for gallstones. As to the untimely operation, the question was not as to the necessity for operation but as to the time it should be performed. In the acute abdomen there were three stages, namely, contamination, reaction, and peritonitis. In some cases by postponement of operation and treatment by palliative measures a desperate case became a safe risk. Personally, when he was in doubt he was inclined to wait. A surgeon frequently in operating found old adhesions that showed that possibly at some time the patient might have been considered a suitable subject for operation and yet had survived without it, so that one could not always say that a patient would die unless an operation was performed. It was better to correct a pathological condition when it was found, however, than to wait for an emergency. In conclusion he agreed with the condemnation of the purge, but he thought morphine had not been given all the credit it deserved. It should not be given while the diagnosis was obscure, but when the diagnosis was once made the patient should have the relief from suffering that morphine would afford. He believed in the Fowler, Ochsner, Murphy treatment.

(*To be concluded*)

Therapeutic Hints.

Glycerin Substitute in Cough Mixtures.—J. Lennox recommends the following substitute for glycerin in cough mixtures:

Irish moss	½ ounce
Water	24 ounces

Boil for 15 minutes, strain, make up to 19 ounces by the addition of boiling water, then add one ounce of glucose, mix, and strain. Where a mucilaginous, demulcent ingredient, agreeable to the taste, is desired this will be found to meet the requirements. The liquid keeps for a reasonable length of time.—*The Prescriber.*

Tickling Cough.—A. Kinsey-Morgan has found the following codein prescription of service in allaying the tickling cough which is so often an annoying after-effect of influenza:

℞	Codeinæ	gr. iss
	Acid. citric	gr. ivss
	Syrup. tolut	ʒiv
	Syrup. prun. virgin	ʒiv
	Aquæ	ʒiv

—*The Lancet.*

Eczema Treated by Rectal Saline Injections.—Percy B. Spurgin cites a case of very severe generalized eczema treated by means of rectal injections of saline solution. A simple soap enema was first given, followed by a rectal saline containing sp. vini gallici i oz. This was retained. A slight improvement was noted the next day, the patient sleeping and taking food better than he did before. Two days later there was a noticeable improvement. Saline and brandy were given every other day, after clearing the bowel with soap enema. The patient was apparently past all hope when this form of treatment was commenced, and the really extraordinary change which took place in a few days was deeply interesting and gratifying.—*British Medical Journal.*

Early Basedow's Disease.—W. H. Foreman of Indianapolis cites a case of early Basedow's disease in which the symptom of vomiting brought the patient to the hospital. Treatment was directed against the hyperthyroidism, but it should be remembered that this condition is often superimposed on an unstable nervous system, and, if the cardiospasm has persisted to the point of hyperplasia and hypertrophy of the cardia, frequent and complete dilatation of the cardia are necessary for the relief of the symptoms. Quiet and rest in bed, with plenty of fresh air and a nourishing diet of liquids and soft foods, with frequent feedings and small amounts at a time, are recommended. Bromides to quiet the nervous symptoms, with quinine and hydrobromide and ergotine for the effect upon the thyroid gland, were used with benefit in the case cited. Where the toxicosis affects the accelerators more than the vagus, as in the case reported, digitalis does little good.

The use of quinine and ergotine is empirical, but he has found from clinical experience that these agents are of value in reducing the goiter, and in reducing or modifying the secretion, modifying or relieving the symptoms. He has used to advantage the following thyrotoxic goiter tablets recommended by Crotti:

℞	Sodium arsenate	0.001 gram
	Sodium phosphate	0. 12 gram
	Salol	0. 10 gram
	Sodium bromide	0. 05 gram
	Calcium oxalate	0. 05 gram

In conjunction with these tablets polyglandular tabulets are used to counterbalance disorders in the respective glands. These consist of the following:

Pituitary gland (desiccated)	0.05 gram
Suprarenal gland (desiccated)	0.05 gram
Pancreas (desiccated)	0.05 gram
Corpora lutea (desiccated)	0.05 gram

—*Indianapolis Medical Journal.*

Bitters.—W. A. Bastedo, in discussing the pharmacology of certain drugs used for stomach effects, takes issue with Carlson, who, from certain experimental observations, holds that the whole value of bitters in medicine is mental and that they are in the same class as an inert but widely advertised patent medicine. Bastedo has noted in many cases of achylia gastrica that bitters have the power to create or increase appetite, though having no effect on the gastric secretion. In many persons with subnormal nutrition, as in convalescence from acute illness, a bitter is useful provided that it is taken not more than five to ten minutes before the time for eating. It acts in achylia gastrica as well as in cases with gastric secretion. In subacidity it promotes the secretion of gastric juice. It should be administered in just sufficient dose to give a strong, bitter taste and not in amounts large enough to have a depressant action in the stomach. If the patient is in a state of normal nutrition, but psychically disturbed about eating, it will be useless. If the appetite is already normal this kind of medication may not only fail to increase appetite but may even lessen it. If the stomach and bowels are deranged bitters may nauseate. The effect on the appetite is solely the local one on the taste buds, therefore it cannot be obtained if the bitters are hidden in capsules or coated pills.—*American Journal of the Medical Sciences.*

A FURTHER CONTRIBUTION TO THE ETIOLOGY OF THROMBOANGIITIS OBLITERANS.*

BY WILLY MEYER, M.D.

NEW YORK.

ATTENDING SURGEON TO THE LENOX HILL HOSPITAL.

1. *Introduction.*—This paper is devoted to a discussion of the disease to which Buerger has given the name of "Thromboangiitis Obliterans." Buerger considers the disease probably due to an infection and suspects as its primary cause a microbic, toxic or other agent, though, as he stated in 1914, his attempts at detecting it had been futile.

The disease is of such frequent occurrence here in New York that most of the members of the Academy have undoubtedly been brought in touch with it. I personally first operated on such a case some thirty years ago, when the disease was still known as endarteriitis obliterans and by a great variety of other names. The terrible mutilation found in its wake, the constantly increasing number and the great sufferings of the patients induced me to make a special study of this mysterious affliction. For some years now I have examined into the disease clinically and of late I have also looked up the literature on the subject. The result of my investigations is, in agreement with the theory of Buerger and others, the conviction that thromboangiitis obliterans represents a poisoning of the system. I ascribe the disease to tobacco smoke poisoning. Had these patients left tobacco alone, whatever other disease they might have developed, they would surely, I believe, not have contracted thromboangiitis obliterans. I maintain, that symptom complexes, similar to the syndrome found in these cases, if not caused by smoking, are not thromboangiitis obliterans, but some other disease.

The feature of tobacco abuse in the history of these cases has already attracted the attention of many observers. But to my knowledge no one, so far, has undertaken to make the abuse of tobacco primarily responsible for the disease—to trace the development of its symptoms to long-continued, excessive cigarette-smoking. That is what I shall attempt to do in this paper.

2. *The Three Stages of Tobacco-Smoke Poisoning.*—The effect of smoking upon the human system shows three stages:

(*a*) The acute poisoning with its well-known symptoms.

*Read before the New York Academy of Medicine, December 4, 1919.

(*b*) The long period of tolerance, with its many times repeated subacute poisonings, and either no symptoms at all, or only such which yield to abstinence from smoking and do not return when the patient commences again to indulge. For the vast majority of smokers, the intoxication ends here. But, if during this stage the absorption of tobacco-smoke poisons into the system exceeds their elimination from the system, the accumulation eventually causes:

(*c*) The stage of saturation of the system with tobacco-smoke poisons, which is heralded by the more or less sudden onset of serious functional and organic disorders. The symptoms may still yield to abstinence, but are, it seems, no longer cured by it; they reappear upon the slightest indiscretion in smoking, apparently having sunk merely just below the threshold of outward manifestation. Once saturated, the system seems to stay saturated.

3. *Thromboangiitis Obliterans, the Stage of Saturation.*—It is in this saturated condition, I claim, that we usually find our thromboangiitis obliterans patients when we first see them. They are *past* the initial stimulating effect of the poisons and have been under their depressing effect for some time. The interval between successive poisonings has been too short for the eliminating capacity of the glands. A vicious circle has set in of the hypofunction of the poisoned sympathetic nervous system, the weakening thereby of the function of the sympathetically innervated glands (kidneys, intestinal, and salivary glands, and the glands of the air passages) which eliminate the poisons, the consequent accumulation of those poisons in the system, and thereby again, the aggravation of the hypofunction of the sympathetic nerves.

4. *Predisposition.*—But, inasmuch as not all those who abuse tobacco to the same extent as our patients have done, are seized with thromboangiitis obliterans, the disease, I believe, clearly demands for the onset of the vicious circle the presence of an additional factor. I look for it in *a predisposition of the nervous system.* As a matter of fact, all the patients seen seem to be thus predisposed. They all are Russian-Polish Hebrews who have immigrated from, or (exceptionally) whose ancestors immigrated from, a narrow belt stretching from the Baltic to the Black Sea. The centuries of persecution under which generations of these Jews have gone there through life in a more or less constantly hysterical condition have left their imprint upon these people. They are neurasthenics by heredity.

5. *Quantity of Cigarette Smoke Inhaled.*—These Hebrews begin to smoke cigarettes when they are twelve to fourteen years of age, or even earlier. Those born here have more likely than not belonged

to that 25 per cent. of underfed New York school children of Dr. Copeland's statistics, and frequently, no doubt, have stilled with smoking the craving of hunger, the cigarette taking the place of the luncheon. The smoking soon becomes a habit and is continued for ten, twenty, thirty years and more, day after day, the consumption amounting to anywhere from ten to one hundred cigarettes in twenty-four hours. They do not smoke cigars or pipe, nor do they chew. The smoking, of course, is not evenly distributed over the twenty-four hours. The patients are mostly members of labor unions. Deducting eight working hours, one hour for meals and seven to eight hours for sleep, there remain seven to eight hours available for the smoking of, say, on an average, twenty to fifty cigarettes. Assume a cigarette to contain 1, 4 grammes of tobacco; assume 1 gramme of cigarette tobacco to develop 2,000 c.c. of smoke; assume one-third of the cigarette to be thrown away and 20 per cent. of the developed smoke to escape into the air unused. Under these assumptions pass, from the stated average of cigarettes, 36,000 to 75,000 c.c. of smoke through the mouth, or—if he inhales—also through the lung of the smoker, that is, in, say, five hours of actual smoking, 120 to 250 c.c. of smoke per minute, or one quart of smoke every four to eight or nine minutes. This gives an idea of what such smoking amounts to on week days, with an extra orgy on Sundays.

6. *The Poisons Contained in Cigarette-Smoke and Their Absorption.*—The absorption of poisons from that volume of smoke, conservatively figured, is:

(*a*) Of nicotine 20 to 50 milligr. for ordinary smoking, and 80 to 200 milligr. for inhaling, inhaling quadrupling the absorption (20 milligr. of nicotine is a dangerous dose).

(*b*) Of cyanic hydrogen 1 to 6 milligr. (60 milligr. being the fatal dose).

(*c*) Of carbon monoxide from 1 to 6 per cent. of the smoke, or from 360 to 4,500 c.c.

(*d*) Of sulphuretted hydrogen 1 per mille of the smoke, or 36 to 75 c.c.

(*e*) Of pyridine about one-third of the nicotine.

(*f*) Of ammonia 5 times the amount of nicotine (100-250 milligr.).

The absorption of tobacco smoke poisons into the system does not seem to depend so much upon the amount and quality of the tobacco used as upon the manner of using it, the absorption rising from cigar to pipe to cigarette. The reason seems obvious. Cigarette smoking requires more frequent aspirations of air. Of the three, the cigarette has the most quickly progressing and, in that sense, the hottest fire, hence the most intense steam development from the moisture in the tobacco, the most effective dry distillation in the zone adjoining the fire and the greatest volume of smoke reaching the mouth of the smoker from a given weight of tobacco within a given time. All these features seem to be factors influencing the degree of absorption of the smoke poisons in the mouth and in the lung of the smoker.

7. *Intermittent Limping.*—By inflicting the effect of such excessive smoking upon an hereditarily weak nervous system, these people have hanging over them, or are actually seized with, the symptom-complex known as "intermittent limping" (*claudication* in French). In the well-to-do among these Hebrews the disease, as a rule, is arrested at this stage, or can be prevented from going beyond it by rest and conservative treatment. But in those not so favorably situated, those who toil with their hands and feet for a daily wage, in these Hebrews the disease often advances to its final culmination: "*gangrene.*" Viewed from this angle, thromboangiitis obliterans is an occupational disease: long-continued exertion of one and the same group of muscles of the upper or lower extremities eventually induces the onset of local gangrene in the exerted extremity. Numerous instances could be cited confirming this observation.

The intermittent limping of thromboangiitis obliterans is intermittent limping of the extremities. But intermittent limping is by no means confined to the extremities, nor is it confined to thromboangiitis obliterans. Generally speaking, intermittent limping is the interruption of the functioning of organs by reason of the temporary insufficiency of their blood supply, either through a permanent loss of caliber of the artery feeding the organ, or through vasomotor spasms which temporarily reduce the lumen of the artery, or through both. The impaired capacity of the artery is still sufficient for the demands of the organ when at rest, but insufficient to supply the larger blood-volume required by the organ when at work. The consequence of this condition is a characteristic cycle of events in cases in which voluntary muscles are the organs involved: the insufficiency of the artery causes ischemia in the active organ, the ischemia causes pain, the pain enforces the suspension of activity, the enforced rest restores to the organ the sufficiency of the blood supply and therewith brings to an end all the symptoms caused by its preceding insufficiency. Upon renewal of the activity a repetition sets in of the same cycle of events.

In the intermittent limping of thromboangiitis obliterans the site of the affected blood vessels is peripheral; in other similar cases it is probably central, the affected arteries being looked for in the anterior or in the posterior portion of the cord. When the blood vessel lesions are in the cord, the disease is not thromboangiitis obliterans. There is a great similarity of symptoms in a variety of diseases of this kind, and some authors have been so much impressed with it that they have called the spurious (functional) angina pectoris "intermittent limping of the heart," and the intermittent limping of the extremities "peripheral angina." We also read of "intermittent limping of the brain," of "intermittent limping of the intestinal tract," etc.

8. *Probable Causes of the Localization of the Disease in the Extremities.*—These considerations suggest the question: Why, under conditions of tobacco-smoke poisoning, are the lesions located in the extremities, and why are the viscera comparatively immune? In view of the observation that exertion seemingly plays an important rôle in determining the part which is seized by the disturbance in circulation, one of the reasons must apparently be looked for in the fact that the extremities are doing the severer part of the work performed by the body. Another reason may be found in the difference in the anatomical structure of visceral and skeletal

muscles, the former being smooth, the latter striated. Not only is the chemistry of their metabolism and their innervation different, but also the character of their blood supply. The smooth muscles, where they occur, are placed within a large reservoir of blood, from which their comparatively small circulatory requirements are readily covered, while the skeletal muscles have the large blood-volume, which they require, carried to them from a distance and have to rely for its sufficiency on the unimpaired vis-a-tergo of the heart as well as on the proper functioning of the blood vessels. It is here that the tobacco-smoke poisons get in their deleterious work.

9. *Collective Effect of the Various Tobacco-Smoke Poisons Upon the System.*—There is first to be mentioned the joint effect of the several poisons, an effect common to all: they interfere in one way or another with the delivery of oxygen to the tissues; they cause more or less tissue-asphyxia.

When in addition thereto intermittent limping sets in, and, in consequence of the insufficiency of the blood supply in intermittent limping, the delivery of oxygen is still further reduced, the oxygen hunger of the tissues must approach a degree otherwise seen only after death in the final tonic contraction of the muscles, when the circulation has stopped altogether. Most likely there occurs in thromboangiitis obliterans in the living tissue of the active muscles what normally happens only in rigor mortis: so large a production of lactic acid, that the available supply of oxygen in the muscular tissue is insufficient to reoxidize all of it promptly, as it does in the active muscle under physiological conditions. Even were the production of lactic acid to remain normal, there would still be a relative overproduction of it by reason of the diminution of the oxygen supply in intermittent limping; there would even then seem to be more acid than the available oxygen could take care of. Such oxygen deficiency would in either event mean free acid. But as there is no chance for the existence of free acid in the system, two chemical actions probably take place: first, the transformation by lactic acid of the neutral diphosphate of potassium (or sodium) of the muscular tissue into the acid monophosphate of potassium (or sodium); second, the transformation in the metabolism of lactic acid, the mother substance of aldehydes, into aldehydes.

Either of these chemical actions, if they actually thus occurred, would be detrimental to the system. The acidity of the nourishing fluid would probably induce plasma-coagulation in the tissue cells; it certainly would also reduce the normal capacity of these cells for oxidizing dextrose. The unassimilated dextrose would then accumulate in the blood and perhaps thus cause the hyperglycemia which we have shown to exist in thromboangiitis obliterans. On the other hand, aldehydes are known to cause intima proliferation in the arterioles and thickening of their muscularis, the very lesions observed in thromboangiitis obliterans.

The lesions resulting from the causes just mentioned seem to show a predilection for such localities, where the network of the small-sized arteries is densest, the arterial blood pressure lowest, and the changes of blood pressure by change of posture greatest: in the tips of the toes and in the tips of the fingers, spots which are also known to be subject to the spastic effect of tobacco-smoke poisons upon the arterioles in acute poisoning. For, although we are dealing with a chronic condition, the acute poisoning also comes into play, because the always renewed excesses in smoking frequently superimpose an acute poisoning upon the saturated system. An aggravated condition of this kind I have seen in a case recently under observation.

The location of the symptoms at the ends of the extremities makes thromboangiitis obliterans appear related to the trophic vasomotor neuroses. All these diseases, such as acroparesthesia, acroasphyxia, erythromelalgia, Raynaud's disease, sclerodactylia, etc., show a predilection for the manifestation of their symptoms at the "acra," viz., the tips of toes and fingers, the point of the nose and of the tongue, the chin, and the ears. The cause of this phenomenon must be looked for in the unequal development of the muscular coat of the smallest and largest arteries, it being greatest in the arterioles, practically nonexistent in the aorta and in the pulmonary artery, with intermediate steps between the extremes, the development decreasing as the arteries grow in diameter. The vasomotor nerves consequently have very little influence upon the largest arteries, great influence upon the arterioles.

10. *Specific Effect Upon the System of the Individual Poisons.*—In addition to the collective effect of all the poisons in combination, each single poison has still its additional specific effect.

A. Nicotine: (a) Specific Effects of Nicotine Upon the Sympathetic Nerves and Their Ganglia.—Nicotine has a selective affinity for sympathetic nerve ganglia, an affinity so pronounced that physiologists determine by means of nicotine whether or not a ganglion belongs to the sympathetic system. Applied in sufficient concentration nicotine interrupts the connection through a sympathetic ganglion of preganglionic with postganglionic nerve fibers by opening the synapse of the ganglion, thus paralyzing it.

As the action of nicotine does not seem to depend on the summation of repeated equal effects, but appears to increase with the concentration of the solution, and as in thromboangiitis obliterans we are dealing with a saturated system, it is my contention that in these patients the *nicotine concentration* is sufficiently great to affect their hereditarily weak sympathetic nervous system and, in the course of time, to put it into hypofunction.

(b) Specific Effect of Nicotine Upon the Adrenals.—Closely related to the sympathetic nerve tissue is the chromaffine* tissue. Both tissues take their origin from the same embryonic cells at a comparatively late stage of fetal development. As a consequence thereof chromaffine cells accompany the sympathetic nerves throughout their extent in accumulations of varying size, so-called paraganglia. The most important of them is the medulla of the adrenal glands. All these paraganglia are supposed to secrete the hormone "adrenalin."

Quantitatively, their secretion is found to depend upon the state of excitation of the sympathetic nerves: when these nerves are in hypofunction—as

*Called chromaffine because of the affinity that this tissue has for chromic acid in microscopic staining.

here assumed for this disease—the adrenals are also in hypofunction.

(*c*) *Indirect Specific Effect of Nicotine Upon the Parathyroids.*—That condition of the adrenals takes us a step further to the parathyroid glands. Experimental proof exists of a probable physiological balance in the blood between the adrenal and parathyroid secretions. As the function of the parathyroids does not seem to depend upon innervation, nerve action as a disturbing effect of the balance, therefore, seems excluded, adrenal hypofunction must be considered equivalent to *relative* parathyroid hyperfunction, though the parathyroids may have remained perfectly normal in every respect, including their function. In other words, the insufficiency of the adrenals becomes apparent as excessive effect of the normal parathyroid secretion; the inhibitory activity of the parathyroids is released, and thereby the functioning of the sympathetic nervous system is further depressed, viz., the adrenal hypofunction aggravated. Here we strike another vicious circle to which the above-mentioned deficient eliminatory function of the kidneys, intestinal, and other glands, which secrete to the surface, may probably be related. The parathyroid glands are supposed to govern the calcium metabolism of the system. It is believed that the calcium content of the blood determines the degree of excitability of the vasomotor apparatus. Consequently, our patients should show vasomotor symptoms. Here again, the theory advanced fits in nicely with our clinical observations. To mention just one, a never-missing symptom: the great pallor of these patients, despite a frequently-found high blood count and a high hemoglobin content of the blood.

The pallor is also otherwise explainable on our theory. Nicotine is known to exert a direct excitation upon the vasomotor center in the medulla oblongata. As in thromboangiitis obliterans, under our assumptions, nicotine is circulating with the blood, the vasomotor center and all the several subcenters—the final ones being probably in the walls of the blood vessels themselves—must be kept in a state of constant excitation which finds expression in vasoconstriction.

(*d*) *Perverse Function of Internal Gland Secretions.*—Experimental proof has been brought which in addition to the presence of hypo- and hyperfunction makes probable the existence of perverse function; that is to say, the normal secretions of healthy internal glands produce the opposite of their physiological effect in diseased or degenerated muscles; *e.g.* in a tobacco-smoke poisoned muscle, or a group of such muscles, the diseased arteries would, under conditions of perverse function, become contracted instead of dilated, whenever that muscle is made to perform work, especially if it is daily exerted and, perhaps, overtaxed. The blood volume reaching the active muscle, instead of being increased, as it should be, would then be decreased below the volume carried to the resting muscle. Such perverse function would go far toward explaining the ischemia of working muscles in thromboangiitis obliterans.

(*e*) *Probable Effect of Nicotine Upon the Pancreas.*—Taking up next the consideration of the effect of nicotine upon the *pancreas*, it can be confidently asserted that, despite the hyperglycemia found by us in every instance, thromboangiitis obliterans patients are not diabetics. They have not got diabetes mellitus; they exhibit neither excessive hunger nor excessive thirst, nor do they ever go into coma, nor is their sugar-tolerance curve of the diabetic type. Nevertheless, the pancreas may be affected in these cases. Experiments are on record in which trophic disturbances of the pancreas were produced by a variety of artificial lesions of the duodenal mucosa. Whether nicotine is an agent capable of doing such damage does, so far, not seem to have been investigated. Apparently the question is answered in the affirmative by at least one case, a recent clinical observation of mine. In a man, thirty-one years of age, with paroxysmal, intense vomiting spells and frequent watery stools, present for over a year, the symptoms could not be traced to any other cause than to chronic nicotine poisoning from excessive cigar-smoking. His blood test showed hyperglycemia, and the sugar-tolerance curve showed diabetic characteristics. The patient was cured by mere abstinence from smoking and no other medication; it was, therefore, a case of non-saturation. The hyperglycemia test was found normal four months later. I venture to construe this interesting observation as a proof that nicotine getting into the stomach and into the duodenum with the saliva is apt to affect the pancreas.

Inasmuch as the pancreas is seemingly a reservoir for potassium, in the sense that the liver is a reservoir for glycogen, the question arises whether under the influence of nicotine the discharge of potassium from this reservoir is of a volume to more than compensate the above mentioned (9) loss of muscular potassium, or whether it just equalizes the loss, or whether it still leaves in the system a deficiency of potassium. Moreover, there is the uncertainty whether lactic acid in the muscular tissue combines with potassium or with sodium. In other words, the question is presented whether the physiologically prevailing potassium-sodium balance of the blood has remained intact, or has been disturbed, and, if the latter, whether the case is one of potassium poisoning or of sodium poisoning.

Observations are found in the literature that in potassium-poisoned dogs the changed chemical composition of the muscular tissue reduces its contractility; the dogs become weak in their hind legs, maintain a sitting posture and tremble when made to stand up. In the light of these facts, might not the quick fatiguing of our patients when walking be explained in part also by a disturbance of the potassium-sodium balance?

I proceeded to investigate this question clinically. In patients whom we treated with duodenal flushing, I added large doses of sodium bicarbonate to the flushing solution; up to 4 ounces of the salt were daily administered for three to four weeks, often up to six weeks. I am not ready, however, to report the results seen. Similarly, iodide of potassium as well as iodide of soda was administered in gradually increasing doses; here, too, results cannot be reported as yet, beyond stating that the pains seemed to yield more readily to the sodium addition than to the potassium addition.

In both instances it may be wise to add atropine and tannin—antidotes of nicotine—to the flushing

solution. Tannin is supposed to reduce the toxic nicotine combinations to harmless salts. Perhaps the addition of a slight dose of phloridzin might also be advisable to break up the imperviousness of the kidneys to sugar, caused by nicotine. Diminution of the hyperglycemia appears desirable, because the circulating excess of dextrose depletes the tissues of fluid and thus increases the viscosity of the blood.

B. Specific Effect of Pyridine.—Of the other poisons contained in tobacco-smoke, pyridine seems to stand next to nicotine in importance. In medium doses it poisons the plasma of the erythrocytes and, by bringing about the separation of the plasma from the stroma, reduces red blood corpuscles to "shadows." Since, as stated, we are dealing in thromboangiitis obliterans with a saturated system, I claim for the pyridine-concentration that it is sufficient to damage the red blood corpuscles as indicated; that lesion would then stimulate the bone marrow to overproduction and furnish a second reason as well for the erythrocytosis already alluded to (10 A. c), as also for the high hemoglobin percentage so frequently observed in patients with thromboangiitis obliterans.

The other reason for bone marrow irritation probably is the tissue asyphxia mentioned above (9); for, the general effect of the oxygen hunger produced by these several poisons is, I presume, more or less the same as that produced by the oxygen hunger occurring through a quick change from low to high altitudes, under which conditions the organism also answers with an increase in the number of erythrocytes and an increase of the hemoglobin content of the individual erythrocyte.

The relationship between the red blood corpuscles and the cells of the endothelial lining of the blood vessels is so intimate that there is no toxic substance known which would damage the one without damaging the other. Hence, it is perhaps permissible to assume that pyridine exerts a deleterious influence also upon the endolethial cells of the arterial intima.

C. The Specific Effects of the Other Poisons Contained in Tobacco-Smoke in Some Volume: Cyanic Hydrogen, Carbon Monoxide, Sulphuretted Hydrogen, and Ammonia.—They are briefly:

(*a*) Cyanic hydrogen (CNH). So small a dose as a 1/20,000 norm. solution of this chemical produces inhibition of oxygenation in the tissue cells.

(*b*) Carbon monoxide (CO). Clinical observations have shown frequently repeated CO poisonings to cause severe alterations of the central nervous system and of the vascular system.

(*c*) Sulphuretted hydrogen (H_2S). In the presence of H_2S the effect of CO upon the blood is intensified.

(*d*) Ammonia. In the metabolism ammonia ordinarily neutralizes acids, but, when introduced into the system in large volume, tends to disturb the physiological sodium-potassium-calcium balance of the blood in favor of calcium. (See 10 A.c.)

11. *Effects of Poisons in General.*—Regarding poisons in general, it has been found that, where the relatively rapid introductin of a poison into the system causes alterations of the media of blood vessels, the same poison, when administered in small doses over long periods of time, produces a pathological condition of the intima of the blood vessels.

12. *Female Immunity.*—If the theory put forth in this paper, viz., the theory that tobacco smoke poisons are the paramount etiological factor in thromboangiitis obliterans, can be upheld, the puzzling mystery of the sex limitation of the disease would have found a very unmysterious explanation: the majority of women do not smoke; at any rate, women do not commit such excesses in smoking as men do.

I thought at one time that menstruation might be responsible for the female immunity; again, that the immunity might be due to the proved antagonism between the male and the female sexual internal secretions. However, I have abandoned these possibilities in favor of the nonsmoking hypothesis.

13. *A Working Hypothesis for Further Discussion.*—I will stop here discussing clinical facts and submitting conjectures for their explanation. The material is so enormous that it is almost more perplexing to determine what to omit than what to report. The ramifications of the subject seem endless. In this brief survey of the whole matter it appeared possible only to land here and there on the summits and throw short glimpses into the valleys. The purpose of my effort is to reveal the vastness of the work still to be done in thromboangiitis obliterans before we can feel that we have touched bottom; also to develop a working hypothesis for that task. This object, I hope, has been accomplished, at least to some extent: for, the theories which I have ventured to submit seem to fit in well with the clinical observations.

14. *Recapitulation.*—If I may briefly recapitulate what has been stated above, I would say:

(1) The characteristics of the patients who are particularly prone to develop thromboangiitis obliterans seem to indicate an hereditarily weak sympathetic nervous system. Hence, the functioning of the eliminating glands (kidneys, etc.), innervated by that nervous system, is probably subnormal.

(2) When the system of such a patient is kept incessantly flooded with tobacco-smoke poisons over long periods of time, the elimination of the poisons by the just mentioned glands is liable to fall behind, and the system will gradually become saturated with the poisons. This is the starting point of the trouble. Vicious circles of various types, a general upset of physiological balances in the blood, tissue asphyxia, etc., are induced, and cause, secondarily, blood vessel lesions which in due course lead to the onset of the symptom-complex known as "intermittant limping" and, under certain conditions, to the culminating development of the disease, "gangrene."

15. *In Conclusion.*—The only real cure for the disease is *prophylaxis.* People so constituted as these Hebrews are *should not smoke.* They should be warned in good season—at home, in school, from the pulpit—of the deleterious effects and serious consequences to them of the excessive use of cigarettes.

Before such a course can show results, many years will have passed by. Meanwhile we shall be called upon to treat these cases. I am strongly of the opinion that, in order to obtain more light upon

the subject, we shall have to break away from the theory expressed in the word "thromboangiitis." I have used the term in this paper in deference to the other participants in the symposium. But the angiitis, like intermittent limping, gangrene, etc., is only *one of the features* of the disease, not the disease itself. The disease proper, in all probability, is of the blood, not of the blood vessels; more precisely, if further investigation should establish as fact the theory here advanced, the disease is caused by the absorbed tobacco-smoke poisons circulating with the blood and in the lymph.

In order to make real progress in the treatment of thromboangiitis obliterans patients, as we meet them in our daily practice, we shall have to concentrate our efforts, it seems to me, upon finding useful antidotes, their proper dosage and the best method of their application. When we have learned how to render harmless in the system, and how to further the elimination from the system, of the several poisons with which these patients seem to be saturated, preventing at the same time by strict injunction against smoking the renewal of *acute* poisonings, we may, I believe, confidently look for results. The treatment of the advanced stage of the disease, with far-reaching gangrene, will, of course, remain operative, as heretofore.

700 MADISON AVENUE.

SUMMARY OF THE CHEMICAL BLOOD FINDINGS IN THROMBOANGIITIS OBLITERANS.

BY ADOLPH BERNHARD.

NEW YORK.

PATHOLOGICAL CHEMIST, LENOX HILL HOSPITAL.

SINCE the literature of thromboangiitis obliterans does not record study of the blood chemistry, a series of investigations of purely biochemical nature were initiated to determine: (1) If there were any changes in the chemical composition of the blood, (2) If any test of diagnostic value could be applied in this disease.

Nitrogenous Constituents. The blood of 15 patients was examined for the non-protein nitrogenous constituents. They were found to be within normal limits, thereby ruling out the possibility of retention of any of these waste nitrogenous substances.

Cholesterol. The cholesterol content of the blood serum was within normal limits.

Chlorides. The chloride concentration of the blood plasma did not vary from the normal figures.

Acidosis. No acidosis was demonstrable, the CO_2 combining power of the blood plasma being normal.

Calcium. The calcium content of the blood plasma showed the normal concentration.

Blood Sugar. A few cases in this series showed a high blood sugar concentration, and this observation led to further investigation. Jacobsen and others have shown that the ingestion of large amounts of glucose produces a temporary hyperglycemia, and often glycosuria. Some workers even state that a definite diagnosis of certain metabolic disturbances can be made from a study of the carbohydrate tolerance. Briefly the sugar tolerance test consists of administering a definite amount of glucose on a fasting stomach and determining the concentration of sugar in the blood and urine, at various time intervals thereafter.

Different investigators, using different time intervals, for the collection of specimens, have obtained in the same disease results which do not agree. The sugar tolerance test was applied in over 300 cases and the technic which has been followed in these cases was used in the investigation of thromboangiitis obliterans. In brief the test consists of administering 100 grams of glucose to the patient on the morning of the test, the patient having had no food since the previous evening. The blood and urine are examined for sugar content before, forty-five minutes, and two hours after ingestion of glucose. The normal concentration of blood sugar at the zero hour varies between 60 and 120 mgs. and may be averaged at 100 mgs. per 100 c.c. We have one case which showed an initial blood sugar of 210 mgs. at the zero hour, without glycosuria.

The normal reaction following ingestion of glucose shows a rise of blood sugar to about 150 mgs. at the forty-five minute period, and a return to or about the original concentration at the end of the two-hour period.

McCaskey has shown that three distinct types of reaction are obtained after the ingestion of glucose. In our investigations of some 300 cases we have also obtained these three reactions and have arbitrarily classified them as type I, II, and III.

Type I starts at about normal figure and reaches a figure of about 200 mgs. at the end of the forty-five minute period and is as high or higher at the end of the two-hour period.

Type II has a normal concentration of blood sugar at the zero hour, and attains a concentration between 150 and 180 mgs. at the forty-five minute period and returns to the normal at the end of the second-hour period.

Type III at the zero hour is about the normal or somewhat higher, but falls to a lower figure at the forty-five minute period with a rise at the end of the second hour.

Our original investigation of the first 16 cases of thromboangiitis obliterans was completed before subsequent investigations resulted in finding the three types of sugar reaction just described. At that time we thought there was a hyperglycemia reaction peculiar to thromboangiitis obliterans. The results of further investigation of the sugar tolerance test on 36 verified cases of thromboangiitis obliterans revealed the following:

1. The blood sugar concentration at the zero hour varies between 96 and 210 mgs. with an average of 115 mgs. per 100 c.c., the urine showing no sugar at the zero hour.

2. The blood sugar at the end of the forty-five minute period varied between 106 and 344 mgs., with an average of 179 mgs., and 36 per cent of the cases showed sugar in the urine at the forty-five minute period, of which 23 per cent. had a lower blood sugar concentration than 150 mgs. Six cases had a blood sugar concentration of 180 mgs. or higher without showing sugar in the urine, and 69 per cent showed a concentration of 150 mgs. or more.

3. The blood sugar at the end of the two-hour period varied between 96 and 288 mgs., with an average of 146 mgs. 33 per cent. showed sugar.

4. In 3 cases, or 8 per cent of all the cases, type I reaction was obtained.

5. 92 per cent of the cases gave type II reaction.

6. In none of the cases did type III reaction result.

In contrast, the series of 300 other cases gave 36 per cent. type I, 55 per cent. type II, and 9 per cent. type III.

THE PATHOLOGY OF THROMBOANGIITIS OBLITERANS.*

By LEO BUERGER, M.D.

NEW YORK.

It was with some reluctance that I accepted the invitation of your Chairman to speak on the pathological aspect of the disease to which I have given the name "thromboangiitis obliterans," for it seemed to me that enough had been said in the past to make this phase of the subject clear. However, I was persuaded to speak in the belief that a graphic review of the histological alterations characteristic of the disease may possibly limit to some extent the promulgation of hypotheses on etiology that are of purely theoretical nature.

I will concede that the exciting etiological factor has not as yet been discovered; nor am I presumptuous enough to suggest that anything more has been done by my own studies than to point out in what direction future researches on etiology should be conducted. My own investigations of the *acute stage* of the disease, thromboangiitis obliterans, warrant me in feeling confident that some specific agent, quite foreign to the many factors, predisposing or otherwise, that have heretofore been held responsible, must be the exciting cause.

I shall point out to you to-night by a series of lantern slides that the disease has two pathological stages that correspond with certain phases of the clinical picture.

*Read before the N. Y. Academy of Medicine, December 4, 1919.

I refer, on the one hand, to the so-called *healed stage* where the thrombotic occlusion of the vessels, both arteries and veins, has given way to organization, canalization, and connective-tissue formation in the occluding clot, with conversion of the arteries by an obliterating process into hard cords; the stage which may correspond with a clinical picture profuse with active symptomatology. For, one must remember, that what is clinically recognized as thromboangiitis obliterans is, as a rule, no longer a syndrome produced by the disease itself, but a combination of subjective and objective phenomena dependent upon impoverished circulation; and that, with all the well-known manifestations, such as intermittent claudication, blanching of the limb on elevation, rubor in the dependent position, trophic disorders, and gangrene well developed, we may still be dealing with arteries that are *healed* so far as the disease thromboangiitis obliterans is concerned.

And, on the other hand, I allude to *the acute stage*, that in which definite evidences of inflammatory processes can be discovered. My histological slides will demonstrate that we are dealing with phenomena that go hand in hand with an active inflammatory invasion of arteries and veins, be they affected in the territory of the superficial vessels or in the territory of the deep: phenomena, that afford the true clue to the investigator for researches on etiology.

When I learn from time to time of the most interesting explanations given by various authors and commentators as to the cause of this malady, I am not a little surprised that individual predisposing factors are dignified by the appellation "Exciting Cause." We have heard much regarding hyperglycemia, or an increased sugar content of the blood, and dyscrasias of endocrine origin, as causative factors; but we must not forget that enough clinical and pathological data are at hand to furnish us with a reliable concept as to what is actually influential in producing changes in the vascular system. By this I mean, that the arteries and veins, *par excellence*, furnish examples of tissue complexes requiring *several factors* for production of pathological alterations. And, strange to say, one or another of these factors (that are merely predisposing agents) are apt to be singled out and heralded as the true cause. When my own pathological studies convinced me that certain specific histological, architectural alterations in the vessels were characteristic of the disease thromboangiitis obliterans, it was not difficult to conclude that a special exciting agent, be it a toxin or organism, must play a rôle here, in addition to the many other conducive circumstances that may play larger or smaller parts. These specific alterations I shall discuss later on, mentioning here only that they occur nowhere else in thrombotic processes and seem to be a pathognomonic for thromboangiitis obliterans, just as the peculiar pathological pictures of tuberculosis are attributable to the tubercle bacillus, and the changes seen in the glands of Hodgkin's disease are doubtless the reactions to special agents.

Reverting to the peculiar reaction of arteries and veins, let me emphasize the fact that more than one factor must be invoked in the case of these peculiar tissue channels. Thus, stasis, locomotion, dependency of the limbs, activity of circulation, vis-a-tergo, tobacco, age, sex, and thermal influences—all these play greater or lesser rôles in determining thrombotic and atheromatous occlusion.

As for tobacco, its influence has been recognized for many years. Erb many years ago in papers written subsequent to his publications on intermittent claudication, attributed extensive atherosclerotic conditions of the lower extremities in the main to the influence of tobacco. Just how far the absorption of tobacco poisons is responsible for the degenerative changes in the arterial walls cannot be determined accurately, but that it may be safely regarded as a predisposing cause, no one will venture to deny. So also in thromboangiitis obliterans, it is possible that the use of tobacco may render the vessels more susceptible to special agents, be they toxic or infectious, but that tobacco is the only and exciting cause is exceedingly doubtful and highly improbable.

Doubtless many of you have seen cases of migrating phlebitis in patients who are heavy smokers, where the territory of the saphenous vein becomes gradually occluded, and where the differential diagnosis between migrating phlebitis of what I term the "bland type" and migrating phlebitis associated with thromboangiitis obliterans must be made. If we exsect a portion of the vein in thrombophlebitis of the *bland type*, we find, it is true, slight changes in the media, but an occlusive thrombus that presents *none* of the characteristic lesions that I shall later describe. In such cases we are dealing with a mere thrombosis, superimposed upon vessels that are damaged by various influences, tobacco or other causes. *In thromboangiitis, however, when migrating phlebitis occurs, certain specific architectural changes can regularly be diagnosticated and found under the microscope.* That something else must call forth or evoke such remarkable architectural complexes seems unquestionably true.

In arteriosclerosis, too, thrombotic lesions occur when the so-called keystone clots close the last remnant of lumen of the partially narrowed vessel. But in this clot the typical lesions of thromboangiitis are absent.

If I were asked to formulate a general concept of thromboangiitis obliterans I should answer as follows: Imagine a patient seeking relief for acutely swollen superficial veins of the lower or upper extremities, of sudden advent, and with all the manifestations of an acute thrombophlebitis. Imagine this process involving a considerable portion of the distal territory of the internal saphenous vein, followed by abatement of symptoms, and consequent resolution or healing. You will be in no doubt as to the general pathology nor as to the clinical course of the condition, though your estimation of the etiology will in most instances, at least, be obscure.

Transfer this picture to the deeper vascular system, over the distribution of the external and internal plantar arteries and veins, the dorsalis pedis, anterior tibial, posterior tibial, and the peroneal arteries and veins, that is, with lesions in territories where objective manifestations are absent—and you will be depicting to yourselves, what corresponds to my own conception of the pathological process in the disease, thromboangiitis obliterans. So here, too, we postulate an acute inflammatory and

thrombotic lesion, but one involving deep arteries or veins, or both, as the initial stage of the pathological anatomy.

Whereas, the patient afflicted with an inflammatory and thrombotic lesion of the superficial veins presents objective signs easy of recognition, the patient suffering from thromboangiitis obliterans in its earlier stages may offer no objective evidences suggestive of the true nature, or of the site of the lesion. It was but in a very few cases of my own series (more than 300) that I felt justified in ascribing certain symptoms to the incipient stage of the disease. Severe, non-localizable shooting pains in the calf or foot, attended with difficulty in walking, or, possibly with tender calf muscles, with or without vasomotor symptoms and coldness in the foot, with or without obliteration of the dorsalis pedis and posterior tibial pulses, may be the only symptoms. It is only when we compare the history with the future clinical course and pathology that we can relegate such indefinite signs to the onset of the affection. In most instances, however, the patient will not seek advice for such initial symptoms, either because they are not sufficiently severe to require the attention of a physician, or because they are incorrectly regarded as rheumatic in origin, possibly due to trauma, cold, the presence of flat or weak foot, or because they are explained on the basis of some other minor ailment.

Strange to say, patients afflicted with thromboangiitis obliterans may present symptoms which differ in no way from those attending the thrombophlebitis of the superficial veins, or so-called migrating phlebitis. These are the cases of thromboangiitis obliterans in which an acute inflammatory thrombosis involves smaller or larger portions of the external or internal saphenous vein, radial, ulnar, median cephalic or median basilic vein. Such cases are the most instructive of all. For they are the ones which afford us material for pathological study. Here the veins are accessible; portions can be surgically removed when the lesions are in the acute inflammatory stage and submitted to histological examination.

While the former type of cases is difficult to diagnose, the variety with concomitant migrating phlebitis can be recognized by a study of the vein lesions under the microscope. If the tissue be examined when the lesions are still in the early inflammatory stage, before organization or healing has taken place, certain characteristic and specific lesions can be identified, changes which I have elsewhere described as pathognomonic for thromboangiitis obliterans.

Having learned that the incipient lesion of thromboangiitis obliterans is an acute inflammatory one, involving the arterial and venous walls, we will expect an occlusive thrombosis as the immediate sequence, and will not be surprised to learn that this stage gradually gives way to one of organization and canalization, resulting in a healed product in which the vessel becomes converted into a cord, more or less adherent to its surroundings, in which even the neighboring nerves may become agglutinated and enveloped in fibrotic vascular cord.

It is the interference with the circulatory conditions of the limbs brought about by the extensive occlusive process that is responsible for most of the clinical manifestations of thromboangiitis obliterans. So that it may be correctly said that patients afflicted with thromboangiitis obliterans do not suffer directly from the disease itself but from the disastrous occlusive thrombosis which signalizes Nature's method of healing a vascular lesion that has long since disappeared.

From a study of the pathological material, and from a comparison of the lesion with the clinical history, we must conclude that insidious or clinically unrecognizable exacerbations of the lesion may occur from time to time, so that the involvement of the vascular territory with the obliterative lesion is a progressive one until the summit of the organized clot reaches the popliteal, in rare cases the femoral or even the iliac arteries. It will not occasion astonishment, therefore, that clinical manifestations, too, become more and more serious as time goes on.

Nor must we be surprised if thromboangiitis obliterans simulates clinical complexes brought about by arterial occlusion from other causes. Differentiation from arteriosclerosis, endarteritic occlusion, and other thrombotic conditions may at times be difficult. It is the fact that thromboangiitis obliterans occurs in *very young individuals* in whom both the vis-a-tergo and the cardiac power are adequate for compensation, and in whom the vascular adaptability is elastic in its scope—it is this fact that accounts for the seemingly almost inexplicable circumstance that gangrene occurs so late, or may be absent, in spite of vast and extensive obliteration of arteries and veins. It is to the development of the collateral circulation, therefore, that we owe, in part at least, the production of a very peculiar, striking, and characteristic clinical picture, recognizable even though manifestations of the acute stage of the disease, or manifestations, such as migrating phlebitis, are absent.

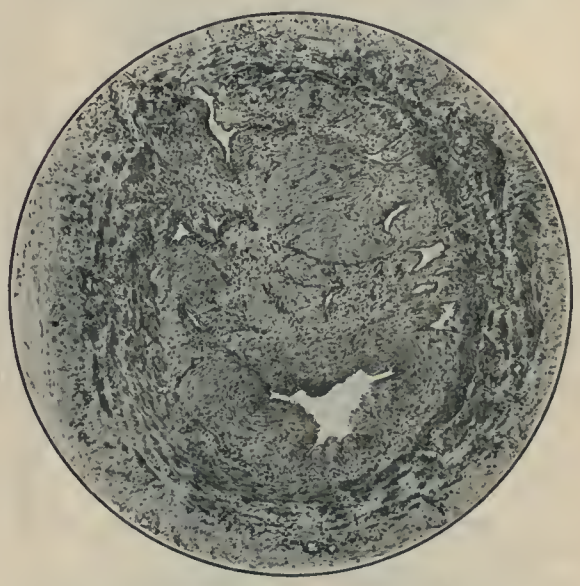

Fig. 1.—"Old" type of occlusion in a deep vein; lumen occupied by vascularized dense connective tissue.

Gross Pathology.—The deep vessels of the amputated legs regularly show an extensive obliteration of the larger arteries and veins. Besides this there are two other lesions which vary greatly in their intensity, namely, the periarteritis and the arterio-

sclerosis. The appearance of the vessels on gross section depends upon the age of the occluding process. Usually the vessel is seen to be filled with a grayish or yellowish mass that can be distinctly differentiated from the annular wall of the vessel,

FIG. 2.—Intermediate stage of organization of occluding clot.

and that appears to be pierced at one or a number of points by an extremely fine opening through which a minute drop of blood can be squeezed (Fig. 1). Such obturating tissue is firm in consistency and does not at all resemble the crescentic or semilunar occluding masses typical of arteriosclerosis. The vessel itself is usually contracted, so that its wall appears somewhat thickened. This picture is characteristic of arteries or veins which are the seat of a very old obliterating process, and is to be found most frequently in the peripheral portions of the vessels, although at times this type of lesion may extend throughout the whole length of the vessel from the dorsalis hallucis into the popliteal.

As we trace certain of the obliterated arteries or veins upward, we are apt to meet with a change in the character of the obturating tissue. Frequently it becomes softer, more brownish in color (Fig. 2), and terminates abruptly in the lumen of an apparently normal vessel. At other times the brownish tissue gives way to soft, reddish masses which are evidently the results of recent thrombosis. In some cases this thrombotic process occupies large portions of the vessel's course; in others it is of short extent and terminates in a long cone of recent thrombus.

The veins share equally with the arteries in the lesion of occlusion. In some cases the veins are more extensively involved than the arteries, and this is particularly true of the collaterals of the posterior tibial, which are often closed when the anterior tibial veins are open. As for the arteries, we usually find an obliteration of a part or of the whole of the anterior tibial; occlusion of the dorsalis pedis, and dorsalis hallucis, of the posterior tibial and plantar vessels, with or without involvement of the peroneal. Sometimes the anterior tibial is practically normal in its upper half or upper two-thirds. More rarely a large portion of the dorsalis pedis is open, with the beginning of the occlusion in the upper part of this vessel or in the lower part of the anterior tibial.

Besides the lesion of occlusion there are two other striking changes, namely, a certain amount of arteriosclerotic thickening and periarteritis. Arteriosclerosis is absent in the younger cases. When present it is never pronounced except in those rare instances in which the patient has suffered from the disease for many years, and has reached the age of forty or more. As a rule, we note but a very slight degree of whitening or thickening of the intima, here and there, in the patent portions of the vessels. In a very few cases small atheromatous patches are present.

A much more interesting and more important change is the fibrotic thickening of tissues immediately about the vessels. Wherever the vessels are occluded there is apt to be an agglutinative process which binds together the artery and its collateral veins, and sometimes also the accompanying nerve, so that liberation of the individual vessels by dissection is difficult. The adhesive condition is due to fibrous tissue growth and varies considerably in its amount. The periarterial fibrosis varies, sometimes being almost absent, at other times so great that isolation of the vessels or nerves becomes impossible and the vascular structures make up one dense rigid cord.

Histopathology.—Let us review the pathological changes in the obliterated vessels in the sequence in which we have met them in the course of our studies, beginning with the most common lesion in the "healed" stage, as it is encountered in the majority of the diseased vessels, removed from an amputated arm or leg.

Such vessels, be they arteries or veins, are filled with connective tissue (Fig. 1) bearing numerous canalizing vessels (Fig. 3), often some pigment of

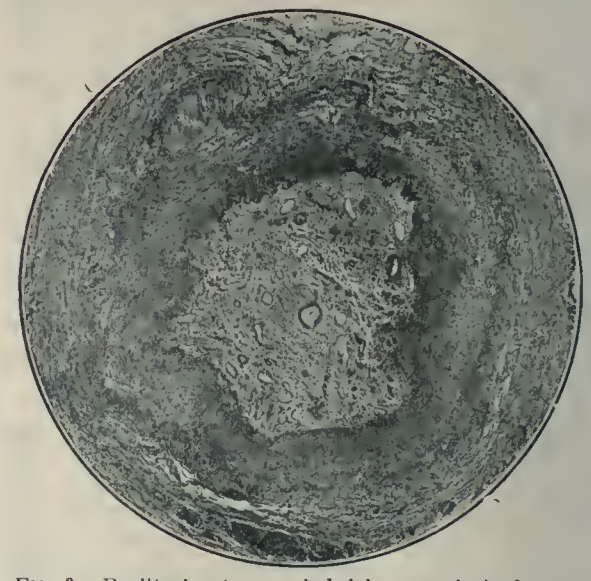

FIG. 3.—Popliteal artery occluded by vascularized connective-tissue pigment, small vessels, and capillaries being features.

blood origin, not infrequently presenting a cribriform appearance in the freshly cut surface of a transverse section (Fig. 4). That the obliterating lesion should have been misinterpreted and regarded as an obliterative endarteritis is not sur-

prising when we look at the pictures afforded by the artery seen in Fig. 5, where a large canalizing vessel simulates a narrowed lumen and crowds the rest of the organized clot to one side. Such a vessel may be seen to divide, if its course be followed

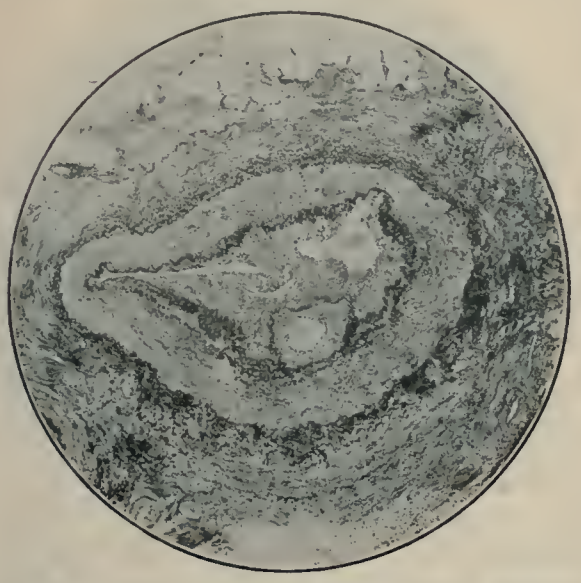

Fig. 4.—"Old" occlusion of the fenestrated or cribriform type; large canalizing vessels in fairly dense connective tissue filling the lumen of an artery.

in serial sections, and the manner of its formation distinctly seen. In Fig. 6, also, there is a vein in which the picture of an endarteritis is mimicked.

All stages of the process, from the finished organized product back to the early thrombotic lesions where arteries and veins are filled with red clot, were studied in the forty amputated legs and two amputated arms. For our purpose here it will suffice to call attention to the earliest or "acute" stage of the disease, as we were able to discover it in the vessels of but two of the forty amputated legs.

In many vessels the wall is diffusely infiltrated with leucocytes, more marked in some places than in others, and the lumen completely occluded by red clot in which certain characteristic foci, elsewhere referred to as "miliary giant-cell foci," make a striking picture (Fig. 7). When these were first encountered in our studies their significance was not understood, except in so far as they seemed unique and specific for thromboangiitis, not having been seen in thrombosis due to other causes.

More recent investigations have clarified our notions, so that to-day a satisfactory explanation can be given for these very peculiar and seemingly "specific" morphological alterations. A change even earlier than this was sometimes found in the deep vessels, namely, foci of pus-cells in the periphery of the red clot, such areas being the precursors of the "miliary giant-cell foci" that resemble miliary tubercles. The suspicion that we were dealing with some specific microbial process was already aroused when the peculiar appearances in deep vessels were noted, not only because such changes had never been seen elsewhere, but also because the typical foci could even be discovered in "daughter" canalizing vessels of arteries that were already in the healing stage. Fig. 8 shows such a specific focus taken from a canalizing vessel that was evidently the seat of an "exacerbation" or "recrudescence" of the disease thromboangiitis obliterans.

Material, however, whose source is confined to amputated members, must needs be difficult to obtain, for seldom will it be our fortune to see the early lesions. Amputation is naturally only considered after the disease has progressed for many months or even years, when the patients are suffering from the mechanical phenomena due to obstructed inadequate vessels rather than from the acute stage of the disease.

It was, therefore, a happy circumstance that the superficial subcutaneous veins of the arms and legs were found to be involved by what has elsewhere been termed an associated migrating phlebitis. From this source we were able to obtain adequate material for the establishment of the facts that the veins under the skin may be the seat of thromboangiitis obliterans; that the acute type of lesion in the superficial veins gives a specific picture similar to that in the deep vessels, and that the development of the lesion in its incipient stages can be studied, enabling us to explain the production of those bizarre appearances heretofore so inexplicable in their nature.

Let us turn to Fig. 9, in which a tributary of the internal saphenous vein presents a purulent focus in a portion of the obturating clot. The rest of the clot is composed of red cells, some white cells, and fibrin already in the process of organization by capillary ingrowth. The purulent focus can be seen to be invaded by leucocytes from the media and adventitia (Fig. 10) and certainly does not represent merely agglutinated leucocytes derived from the intravascular blood.

Such foci vary in size, and it can be definitely established that their growth occurs by virtue of

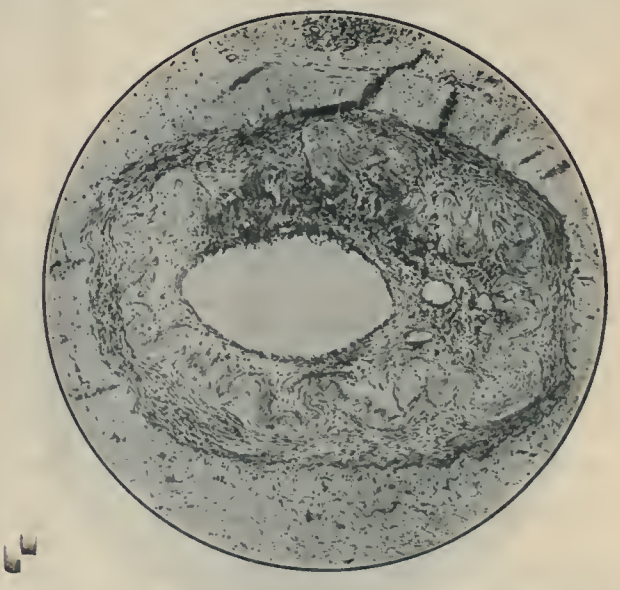

Fig. 5.—"Old" occlusion in artery simulating "endarteritis obliterans"; eccentrically situated large canalizing vessel crowding rest of tissue to one side (to the right in the illustration).

the immigration of leucocytes. Next in the life history of the lesion comes an attempt at healing these suppurative areas, and in this process are found those characteristic and peculiar pictures elsewhere called "miliary giant-cell foci." Evidently

the microbial agent, toxin or whatever it may be, is concentrated especially in these areas.

Here it is instrumental in attracting leucocytes into the formation of miliary abscesses, and it may

Fig. 6.—New lumen found in organized clot in vein simulating endarteritis obliterans (elastic tissue stain).

exert a more protracted force or influence in preventing that orderly and typical organizing process that is so characteristic and so well known. Instead of the rapid ingrowth of angioblasts with the production of young capillary sprouts, the vessel-forming cells (angioblasts) seem to lose their power of purposeful penetration into the suppurative areas—grow wild, as it were, become distorted and atypical, and arrange themselves along the periphery of the foci in the form of cells that we recognize as "endothelioid." Often they can be seen penetrating for a considerable distance into the leucocytic focus—fraying out, never able, at this stage, to produce capillaries. On the other hand, they do frequently terminate in the production of the typical giant-cells. This is the earliest stage in the attempt at organizing or healing these miliary foci.

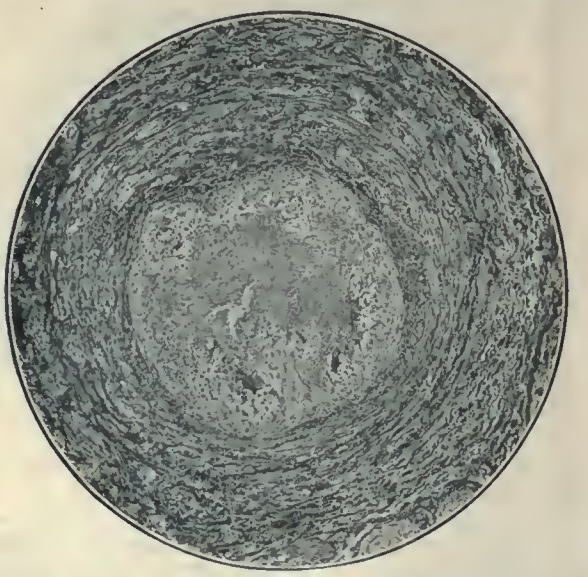

Fig. 7.—Acute, early lesion with "miliary giant-cell foci" in periphery of clot filling lumen of deep vein.

At the same time, the typical successful organizing process may be found going on in other parts of the lumen of a vessel. Thus, in Fig. 9, the crescentic area adjacent to the miliary focus is occupied by red clot and fibrin, successfully and normally organized by angioblasts.

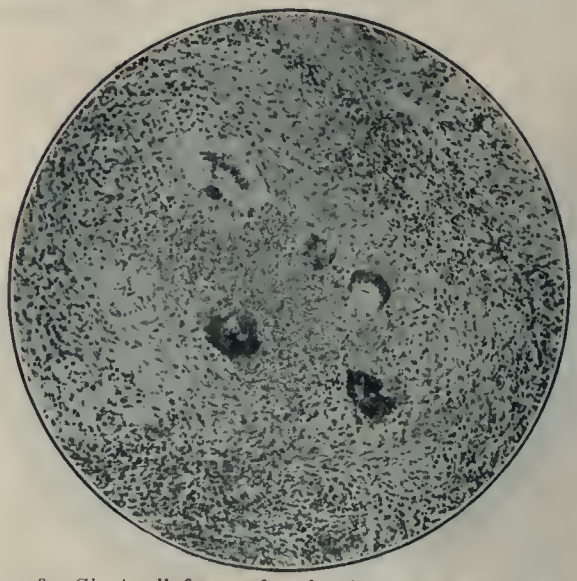

Fig. 8.—Giant-cell focus of a daughter-canalizing vessel in obliterated artery; acute exacerbation in canalizing vessel.

Later, as the giant-cells arrange themselves about the periphery of the focus and penetrate it to a certain extent, the leucocytes disintegrate, and finally a tubercle-like formation (Fig. 11) is the result. The purulent products become absorbed, and the focus becomes converted into connective tissue.

The giant-cells and endothelioid cells are but the expression of abortive attempts on the part of the angioblasts at organizing or healing a focus which is infectious. The true purpose of the vessel-forming cell (angioblast), at times so beautifully illustrated in other parts of the same vessel lumen, is thwarted.

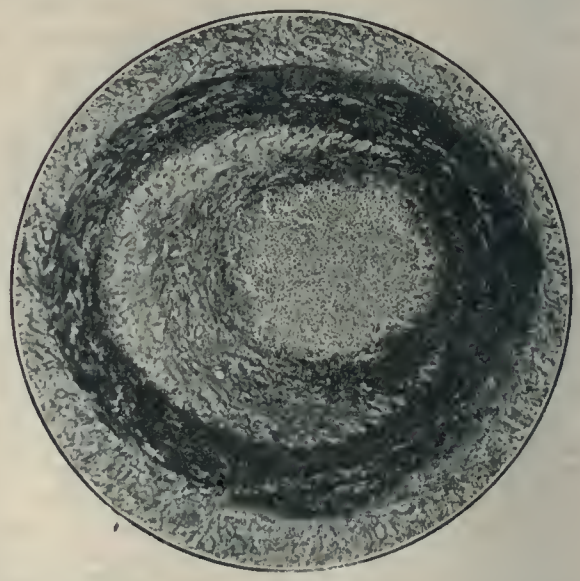

Fig. 9.—Acute lesion in internal saphenous vein; on the right, purulent focus; on the left, remaining crescentic portion of lumen filled with organizing clot.

Later, all vestiges of the acute lesion disappear. The occluding thrombus becomes converted into

vascularized connective tissue. The leucocytes and wandering cells disappear from the media, adventitia, and perivascular connective tissue, an obliterated, canalized, and adherent vessel being left as the final product.

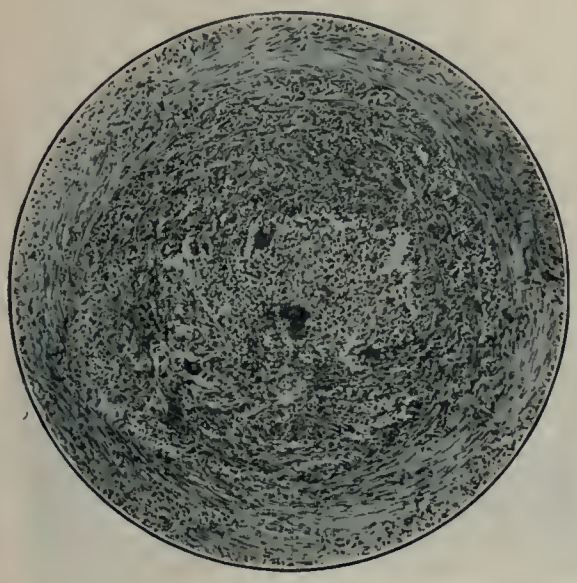

FIG. 10.—Acute lesion in superficial vein; media infiltrated giant-cell focus.

Such, then, are the acute lesions in the veins. They bespeak the presence of a microbial agent that must be sought for in the peculiar characteristic foci previously described. Up to the present time, all our attempts at detecting the causative agent have been futile.

Spirochaetæ, tubercle bacilli, the ordinary pyogenic organisms, have been carefully looked for in cultures, in microscopic sections, and by inoculation methods, without result. However, the search must not be given up, since but relatively little of

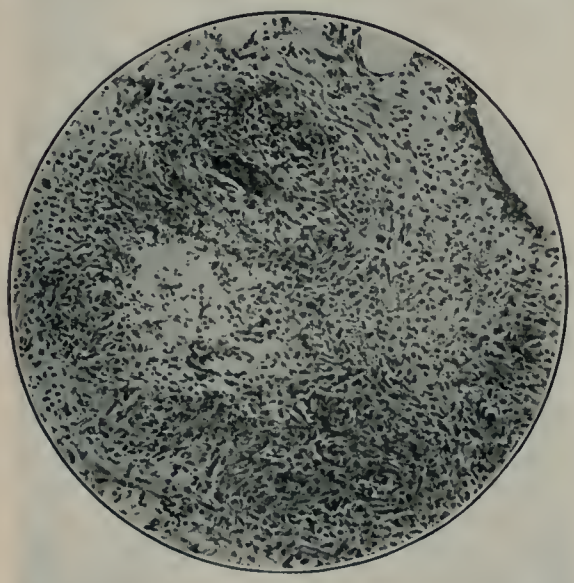

FIG. 11.—Later stage in "acute lesion," simulating miliary tubercle endotheliold cells and giant cells surrounding focus of disintegrating leucocytes.

the "acute" material has as yet been available for study.

Although, in this rapid review of a subject which still presents so many mooted points for investigation, it has been impossible to give all the details which support the theory advanced, it is hoped that a vigorous plea in favor of the correctness of the following points has been made:

First, that thromboangiitis obliterans is a disease in which an acute inflammatory lesion and occlusive thrombosis of arteries and veins are the characteristic lesions.

Second, that from the mechanical point of view and from the standpoint of symptomatology, the thrombotic occlusion is the most important phenomenon.

Third, that the thrombosis is probably preceded, and certainly accompanied by an acute inflammatory or exudative stage.

Fourth, that the lesion involves deep veins in about 40 per cent. and the superficial veins of the upper and lower extremity in 20 per cent., of the cases.

Fifth, that recent investigations of the veins show that the acute lesions in the superficial vessels and the deep vessels are identical.

Sixth, that the histological changes in the veins point to the existence of an infectious process.

Seventh, that we believe that future studies should be directed toward the discovery of the causative agent in specimens cut out from the superficial veins when they are the seat of the acute thrombophlebitis. In this way it is hoped that the etiology of the disease may soon become revealed.

In short, the lesions in thromboangiitis obliterans are in chronological order: (1) an acute inflammatory lesion with occlusive thrombosis, the formation of miliary giant-cell foci; (2) the stage of organization or healing, with the disappearance of the miliary giant-cell foci, the organization and canalization of the clot, the disappearance of the inflammatory products; (3) the development of fibrotic tissue in the adventitia that binds together the artery, vein, and nerves.

1000 PARK AVENUE.

URETERAL KINKS AND THEIR SIGNIFICANCE.

BY F. A. ROBERTS, M.D.

NEWARK, N. J.

MODERATE hydronephrosis is often overlooked. It is usually associated with abnormal mobility of the kidney and consequent kinking or angulation, or, in congenital cases, with the insertion of the ureter at the upper and median border of the kidney, producing a complete or incomplete obstruction to the outflow of urine from the kidney pelvis. In cases where the kinking is in the continuity of the ureter, irritation is produced, with a narrowing, and consequent dilation and back pressure in the kidney pelvis, thereby producing a place of least resistance and invitation to infection with the convertion of a hydronephrosis into a pyonephrosis.

It is a well-known fact that a hydronephrosis may exist a long time before it is recognized. I firmly believe, however, that Nature often holds out her hand, giving us a gentle hint, and we fail to grasp it. Strychnine, belladonna, and arsenic are very poisonous drugs, but before poisoning takes place, symptoms tell us when to stop the administration, and if these symptoms are heeded, fatal poisoning cannot take place. So it is with many

kidney cases; with all the modern urological instruments, functional tests, skiagraphy, and *x*-ray, there should be little chance for mistaken diagnoses. It is true mistakes are made at times, and will continue to be made, but if we use every means at our command, not in a haphazard, but in a systematic way, then we have not committed the sin of omission at least.

Frequency of urination is only a symptom, yet if due to a urethral stricture, I am sure it is not as dangerous as if produced by a tuberculous pyelitis. To tell the patient with frequency of urination that he has a cystitis means nothing—nothing but a haphazard guess by the physician and a dangerous delay for the patient. It is not necessary to give all details in the conditions of frequency—I simply jumped from the penis to the kidney as the two extremes. The intermediate causes are well known to every urologist. Therefore, we must consider frequency in its infancy, if we wish to serve the patient best.

Also, clear urine is no indication that disease is not lurking somewhere in the complex genital apparatus. How many men have been advised to marry (after consulting their physician) on the appearance of a clear and sparkling urine—and with the well-known disastrous consequences? Carefully note all the symptoms, objective and subjective, in every given case. Symptoms are sometimes misleading. Congenital anomalies of the kidney and ureter are more frequent than commonly supposed, as cases illustrated will show.

Lesions in the right lower quadrant of the abdomen sometimes give rise to obscure symptoms, and a differential diagnosis between appendicitis, stone in the ureter, and stricture must be made. An adherent appendix will sometimes cause a ureteritis, and even a pyelitis. A retrocecal appendix with adhesions to the ureter will cause frequency of urination.

Dystopic kidneys are usually congenital and before the use of the shadowgraph-catheter and pyelograph clinical symptoms pointed to some pathological lesions in the abdomen other than the kidney. The shadowgraph-catheter shows an appreciable difference in the length of the ureters. It will also clear up doubtful cases of retroperitoneal conditions. The usual symptoms produced by a misplaced kidney are disturbances of the digestive organs, and during the excursion, the ureter becomes twisted or kinked, severe pain in the kidney due to obstruction (the obstruction in a hydronephrosis may be complete or incomplete), to the flow of urine down the ureter to the bladder and consequent damming of urine in the kidney pelvis, causing a hydronephrosis or, if infection takes place, a pyonephrosis.

Ureteral bends or kinks producing the irregularities of the ureter are a factor in producing not only renal symptoms, but also nephrolithiasis. Hydronephrosis occurs from causes within and without the urogenital apparatus. In early hydronephrosis, cystoscopic examinations do not give a positive diagnosis, nor even suggest one. Pyelography is the only means to that end.

The following are some illustration cases:

Fig. 1.—Skiagraph of ureteral catheter shows a displaced kidney.

Fig. 2.—Showing abnormal attachment of ureter to the renal pelvis.

Case I.—F. A., age 49, single, hotel worker, has complained of pain for 30 years, since an injury to the groin and testicles; the pain is in the right upper and lower quadrant of the abdomen, as well as in the epigastric region; it disappears on eating, and when it is severe this is the only means of relief. He had his appendix

Fig. 3.—Showing a mist in the left ureter.

Fig. 4.—Case III. Ureteral kinks.

removed at a Philadelphia hospital, as he was told he had chronic appendicitis. At time of operation the gall-bladder was examined for gallstones; the lesser and greater curvature of the stomach, as well as the duodenum, for ulcer, with negative results. The operation failed, however, to relieve him of his pain. He now thinks he has a stricture. Added to the above symptoms, he has frequency of urination by day, none at night; the force of the stream is small. Examination shows urine clear, the prostate and vesicles negative, the urethra also negative no residual urine.

Cystoscopy: trigone normal, bladder trabeculated, which made it difficult to find the ureteral openings, the left being no larger than a pin-point. The *x*-ray shows the shadowgraph-catheter deviating from the normal path to the kidney, swerving inward toward the median line, and at the 2d lumbar vertebra takes a right angle turn to the right, then downward. So far, we know we have a dystopic kidney, but the diagnosis is not complete. (See Fig. 1.).

The next picture shows the kidney pelvis injected, giving a clear outline of the kidney pelvis, the major and minor calyces, also the insertion of the ureter at the upper and median border, instead of the normal attachment to the lower and median border. The picture (Fig. 2) shows beginning hydronephrosis.

A double synchronous pyelography was not attempted owing to the fact that the patient stood instrumentation poorly.

Case II.—Mrs. O. B. Pain in bladder since last confinement three years ago. Periodical relief, frequency of urination and attacks of renal colic.

Cystoscopy is negative except for trigonitis. Both ureters catheterized—specimen negative for both the colon bacillus and the tubercle bacillus. The shadowgraph-catheter shows a decided complete twisted left ureter. (See Fig. 3.).

Case III.—J. F., aged 25, single, complains of frequency of urination by day and night. No pain, no blood. Venereal history negative. Prostate and vesicles normal. No stricture. External genitals normal. Prostate and vesicles negative. Urine clear.

Cystoscopy shows the bladder normal except for slight trigonitis; right ureter opening normal; left larger and showing continuous dropping. The ureters were catheterized, but the specimens were negative. The *x*-ray and shadowgraph-catheters shows wrong insertion of the ureters and ureteral kinks. (See Fig. 4.)

30 East Kinney Street.

A NEW METHOD OF PHAGOCYTOSIS TEST, WITH THE BLOOD PLASMA,

A SPECIFIC IMMUNOLOGICAL REACTION

By MORISUKE OTANI, M.D.,

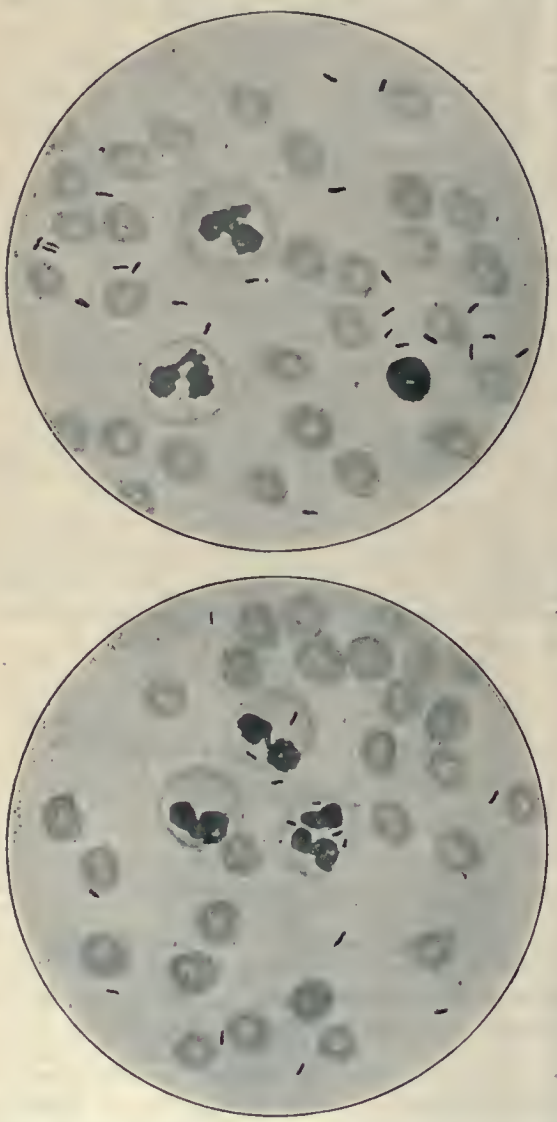
TOKYO, JAPAN.

CHIEF OF THE CLINICAL DEPARTMENT OF THE KITASATO INSTITUTE FOR INFECTIOUS DISEASES.

The citrated or oxalated blood plasma of cases infected by a certain species of pathogenic microorganisms has been found to have a remarkably augmented phagocytal power against that particular species of microorganism. This acceleration of phagocytosis may be considered to be one of the immunological reactions, by means of which an early diagnosis of tuberculosis, typhoid fever, and dysentery may be established. The method dealt with herein is by far simpler than Wright's opsonin test. It can be easily applied, therefore, for clinical purposes as well as immunological investigation.

Apparatus and Chemicals.—1. Glassware: Fresh glassware shows an alkaline reaction, which exercises an unfavorable influence on various immunological reactions and it is often the source of an unexpected failure, especially when complements are used. Leucocytes are also influenced by the alkalinity of the glassware; their movements will be considerably impeded by it. All the glassware for the test must, therefore, be thoroughly washed

before use. I wash the glass tubes, of which Wright's capillaries and also his blood collecting tubes are made, by passing the tap-water through them at least for 3 hours. Wright's capillary must not be too thin. It is made most conveniently of a glass tube having a diameter between 5-6 mm. It must be washed with physiological saline immediately before use, and the water must be removed as perfectly as possible, but not necessarily by heating. The blood-collecting tube should be made of a glass tube having a diameter of 4 mm. If it is too fine, the mixing of the blood and the sodium



Phagocytosis after the citrated blood method with the typhoid bacillus. The upper figure shows the result with normal blood (control); the lower figure shows the result with the citrated blood of a typhoid patient.

citrate will not be complete and coagulation of the blood may result. If it is too wide, on the other hand, the measurement of the withdrawn blood becomes very difficult. Finally, a paraffin dish is necessary to mix the materials for the examination in it.

2. Blood Collecting Needle.—The blood collecting needle that is used in our laboratory has a lancet shape. It is covered with a metal sheath and exposed only at the cutting edge. The length of the exposed end can be adjusted by a screw that is attached at the basal end. The edge must be kept sharp. A sharp needle will easily cut open the wall of the capillary blood vessels and facilitate the collection of the blood. If the blood oozes too slowly, coagulation will occur and the material will be unfit for the test. By means of this needle, it is easy to obtain 3.0 c.c. of the blood from the tip of the finger.

3. Hanging Water Bath.—The materials for the test are mixed and then allowed to stand at 37° C., for a certain period of time to allow them to interact. This may be done by putting the vessel in an incubator at 37° C., but a water bath is more suitable for the purpose, as water conveys heat more quickly than air. In my laboratory, a hanging water bath, 1 ft. 2 in. by 4 in. by 5 in. in size, provided with a glass adjuster, is used. But an ordinary water bath may serve the purpose well or even a drinking glass filled with water at 37° C. can be substituted.

4. Sodium Citrate.—The sodium citrate on the market is not pure enough. A preparation having an acid reaction is unfit for the purposes. It can be purified in the following manner: Crystallized citric acid is dissolved in warm distilled water. The solution is neutralized with a 10 per cent. caustic soda solution, and the reaction is tested with litmus paper. Then a small part of the solution is taken, to it is added some phenolphthalein, and it is then boiled a little while. If the solution takes a faint pink color, the neutralization is said to be exact. The neutralized solution is then filtered, put in a porcelain dish, and evaporated on a water bath until crystallization takes place. The solution is then cooled down at room temperature. Absolute alcohol is added in order to facilitate the crystallization. The crystals are then collected on filter paper, washed two or three times with absolute alcohol, and dried in a porcelain dish on a water bath. The crystals of sodium citrate thus purified are pure white, dissolve in water with a neutral reaction, and have a strong power to prevent coagulation of the blood. The container must be kept tightly corked.

Preparation of the Materials for the Test.—1. In the first place the "citrated blood" is prepared. It is a mixture of a 0.1 c.c. of 2 per cent. solution of sodium citrate and 0.2 c.c of the fresh blood. The 2 per cent. solution of sodium citrate is made by dissolving 2.0 gm. of the crystals together with 0.85 gm. of table salt in 100.0 c.c. of distilled water. The solution is divided in test tubes and autoclaved.

To collect the blood, take the blood-collecting tube in the left hand and a 1.0 c.c pipette in the right. Fill the pipette with the citrate solution. Then keep both tubes in a horizontal position while the open ends are kept in contact with each other. 0.3 c.c. of the sodium citrate solution is then made to flow into the tube by elevating a little the open end of the pipette. The level of the sodium citrate solution in the blood-collecting tube is marked with a glass-pencil. Then similarly 0.2 c.c. of the citrate solution in the tube is poured back into the pipette, leaving just 0.1 c.c. behind in the tube.

Then the tip of the finger of the person whose blood is intended to be tested is wiped thoroughly with a piece of cotton soaked with alcohol. The cleansed finger is then pricked by means of the needle above mentioned. If the hand is very cold,

it is better to dip it in warm water before the prick is made in order to get better blood circulation. The oozing blood is sucked up into the blood-collecting tube by means of the capillary attraction from the end, where the citrate solution remains. The blood is sucked up until the contents of the tube just reaches the mark of 0.3 c.c. The collection of the blood must be carried out in as short time as possible, lest coagulation take place during the operation. Squeezing the finger will help the oozing of the blood a great deal. When the required amount of the blood is sucked up, the tube is revolved quickly around its long axis in order to mix thoroughly the blood and the citrate solution. Then the other end of the tube is sealed over the flame. The tube is now cooled as quickly as possible and is shaken just as the thermometer is shaken to get the filament of mercury to settle down. Thus the fluid that has settled down at the sealed end of the tube is completely mixed. Special care should be taken in collecting the blood into the tube, not to allow the citrate solution to get to the opposite end of the tube, for it will interfere with the sucking up of the blood. The tube must, therefore, be held in a nearly horizontal position, but so that the blood-receiving end is somewhat higher than the other. If coagulation occurs in the collecting tube while the blood is being collected, it will be unfit for the test. This is because by coagulation the normal opsonin, which is non-specific, will be set free in the solution, and the results of the test will become unreliable.

2. Blood Plasma.—The blood plasma is obtained from the citrated blood by centrifugalization or simply letting it stand. It can be kept intact in a refrigerator for two weeks.

3. Leucocytes.—In testing the human blood, the above described citrated blood and the leucocytes in it can generally be employed directly as such. But in the test with the plasma against tubercle bacillus or staphylococcus, really normal blood being very difficult to obtain, or in the test for some other special purposes, the leucocytes must be washed in the following method: The blood oozing at the tip of the finger is allowed to drip on the surface of 7.0 c.c. of a 0.7 per cent. sodium citrate solution, which is contained in a centrifugalizing tube. In introducing the blood into the solution, care should be taken not to allow the blood to run down along the wall of the tube, but to fall directly into the solution. The blood and the citrate solution are then well mixed by shaking, the blood corpuscles are separated by centrifugalization, and the supernatant fluid is removed by a capillary pipette. The leucocytes thus obtained are said to be "non-washed leucocytes" for convenience sake. "The washed leucocytes" are obtained by washing them once with physiological saline. These washed leucocytes are employed in the test for opsonin and tropin. The non-washed leucocytes and the washed leucocytes have been found not to be the same in their properties.

4. Bacillary Suspension.—In preparing the bacillary suspension for the test, a strongly virulent strain should be employed. If a less virulent strain of tubercle bacilli, for instance, is used, there will be no difference between the results of phagocytosis in both normal and infected plasma. Again, a weakly virulent strain of typhoid bacilli will be digested by the lecocytes and the counting of the phagocyted bacilli will be made very difficult. With the typhoid group of bacilli, *B. dysenteriæ* and *B. coli*, an 18-hour old agar culture is employed. The strength of the suspension being just 1.0 mgm. of the bacilli suspended in every 1.0 c.c. of a 1.5 per cent. sodium citrate solution prepared with physiological saline.

In the case of tubercle bacilli, the suspension is prepared in the following manner: The bouillon culture of a very strongly virulent strain is employed. The form and the antacid property of the bacilli are first examined. I always employ a strain preserved in our laboratory and known as the Frankfort strain. Smeared preparations are made of its fresh culture and stained with Ziehl's mixture. They are then decolorized with alcohol and hydrochloric acid mixture and restained with a mixture of borax and methylene blue. If there are too many bacilli unstained by this method or if they do not present a good form, they are not good for the purpose. If they are provided with these requirements they are heated at 80° C. for one hour and the bouillon is removed by means of a capillary pipette. To the remaining bacilli, physiological saline is added and the mixture is lightly shaken. The saline solution is again removed by a capillary pipette. The bacilli are then pounded lightly in an agate mortar for ten minutes. Physiological saline is then added and the pounding is continued as before. The ground up mixture is now centrifugalized at 2,000 revolutions per minute for 30 minutes, and the supernatant milky fluid is removed into a test tube with a capillary pipette and diluted with the physiological saline. It is diluted so as to present the same turbidity as the emulsion of *Staphylococcus albus* that is prepared by emulsifying 2.0 mgm. of an 18-hour old culture in 1.0 c.c. of physiological saline. The suspension of tubercle bacilli thus prepared is again diluted with an equal volume of a 3 per cent. sodium citrate solution prepared with physiological saline. The suspension will thus contain 1.0 mgm. of the bacilli in each 1.0 c.c. It contains also 1.5 per cent. sodium citrate and 0.85 per cent. sodium chlorate. The suspension thus prepared is put into a glass tube, hermetically sealed, and heated at 65° C. for 30 minutes. The heating is repeated for 3 succeeding days. It can then be kept intact in a refrigerator for 5 months. The suspension must be tested of its integrity before it is used for the testing of a patient's blood plasma. Before opening the sealed tube, it must be first shaken in order to get a perfectly homogeneous suspension. This can be done most conveniently by quickly rolling the tube between the two palms.

Mixing the Materials for the Test.—I. Citrated Blood Method: For the testing of human blood, this method is most conveniently applied. The materials should be mixed in the following proportions: Citrated blood to be tested, 2 volumes; Bacillary suspension, 1 volume.

To mix these two fluids, take a Wright's capillary and mark a line at a place about 2 cm. distant from the end of the capillary. Fill the capillary with the citrated blood up to the mark, then

allowing a little bubble of air to get into the capillary the same citrated blood is again allowed to rise in the capillary up to the same mark. The end of the capillary is then wiped with a piece of clean gauze and the bacillary suspension is introduced into the capillary up to the same mark. The entire content is now blown out into the paraffin dish, the blowing being made by means of a rubber cap. The fluid is then repeatedly sucked up into the capillary and blown out into the dish to ensure as perfect a mixture as possible. Lastly the entire fluid is sucked up into the capillary, this time the capillary being kept empty up to the mark. Care should be taken in doing this that no air be mingled with the sucked-up fluid. The end of the capillary is then sealed hermetically and put in the water bath at 37° C.

The reason why 2 volumes of the citrated blood is employed in this mixture is that by this the number of leucocytes in the test fluid should be sufficiently great so that the counting of the phagocyted bacilli can be made easier. This method is applicable for the testing of human and horse blood, but not of rabbit and guinea-pig blood. The leucocytes of the latter animals will be destroyed by the treatment. The citrated blood should be mixed with the bacillary emulsion within at least 2 hours after its collection, because the phagocytal power of the leucocytes decreases with standing.

II. Blood-plasma Method.—The blood of a patient having leucopenia, *e. g.* one with typhoid fever, must be tested by this method. It can also be applied when the test is necessarily made after a longer time than the first method requires. Therefore, this method is especially useful for the laboratory test. As is stated above, rabbit's and guinea-pig's blood cannot be tested by the first method, but it can be tested by this method. Moreover, in the former method, the normal leucocytes are necessary for control. Difficulty is met with in carrying out the phagocytal test with the control test, because it would be very difficult to obtain the number, sorts, phagocytal power, etc., of the leucocytes of both the patient and the control under the same conditions. With diluted blood plasma, this method alone is applicable.

With this method, there are two different systems of the test. These differences arise from the use of citrated normal blood and non-washed leucocytes. For convenience sake they are called methods A and B. Method A is applicable when a genuine normal blood is obtainable and when the blood of a typhoid or dysenteric case is to be tested. Method B is employed when a genuine normal blood cannot be obtained and when the blood of a tuberculous case is to be tested. The following shows how these two methods differ from each other:

Method A { Blood plasma to be tested, 1 volume. / Citrated normal blood, 2 volumes. / Bacillary suspension, 1 volume.

Method B { Blood plasma to be tested, 1 volume. / Non-washed leucocytes, 1 volume. / Bacillary suspension, 1 volume.

The control test for each of these two methods is as follows: The blood plasma to be tested is replaced by the same quantity of a 0.7 per cent. sodium citrate solution. The non-washed leucocytes, as they are employed in Method B, may contain some blood plasma, but as it is diluted more than ten times the original concentration and especially as it is diluted less than one half the volume of the suspension, it does not interfere with the results. Indeed, the blood plasma of a tuberculous case has been found to give generally a negative phagocytosis in this dilution. The results of the control examination with Method B have never given more than 10 per cent. of the phagocytal index. When it is sometimes necessary to dilute the blood plasma, this should be with a 0.7 per cent. sodium citrate solution, which is prepared with physiological salt solution. If it is diluted with the physiological saline alone without the citrate, non-specific opsonic action may sometimes be met with.

If we compare the results obtained by the methods I and II, we generally see that the Method I produces more remarkable results than the other. This may be due to the higher concentration of the blood plasma in the material. But it must be owned that sometimes a higher phagocytal index is obtained with Method II than with Method I.

Preparation of the Microscopical Slides.—1. Smearing:—The mixture of the materials to be examined, prepared after the methods described above, is put in the water bath at 37° C. (or in an opsonizer or the like) for a certain period of time. The time varies according to the species of bacteria, for instance, 20 minutes for the tubercle bacillus, 15 minutes for the dysentery bacillus, and 10 minutes for the bacilli of the typhoid group. The last mentioned bacilli are sometimes influenced by the blood plasma and destroyed to a greater or less degree, especially when blood or the blood plasma of a patient is employed. This may be due to the bacteriolysin in it, which is kept active throughout the entire course of the test.

When the capillary has been kept in the water bath for the required length of time, it is taken out and the rubber cap is removed. It is then cut open at the empty end with a file. The contents are emptied into the dish and well mixed and the microscopical slide is prepared. The smear may be prepared on the object glass after Wright's method, but I should prefer the following: Take two cover glasses each held with cover glass pincers. Hold one of the cover glasses with the right hand and put a small drop of the mixed fluid on one corner of it. Then hold the other cover glass with the left hand. Put the right hand cover glass on it, so as to facilitate the distribution of the mixture between these two. Then the right hand cover glass is moved with the pincers. In doing this, both glasses must be kept parallel and no cracking sound should be made, otherwise some of the leucocytes may be destroyed. In order to ensure the even distribution of the leucocytes on the glasses, raise first one then the other glass alternately, at the time burning the glasses so as to ensure a thorough distribution of the fluid on them. By this method, the leucocytes on the glass will be made to stand out separately. This must be done thoroughly, for if there should be an agglomerated mass of the leucocytes on the glass, it would be very difficult to distinguish whether the bacilli are englobed in the leucocytes or not.

2. Fixation and Staining: The fixation and the

staining vary according to the different species of bacilli examined. The following are summarized descriptions of these individual methods:

A. Tubercle Bacillus: The smeared glass is dried in the air and fixed by passing through the flame. It must not, however, be overheated. It is then carefully stained with Ziel's fuchsin and carbolic acid mixture. If during the process of staining the glass is cooled and a precipitate is formed, it must be heated until the fluid becomes again clear. After cooling, the stained fluid is decanted off and the preparation is decolorized. The decanted staining fluid may be conveniently poured over to the next preparation, because it has a stronger staining power than a fresh one. In this way, a series of slides may be stained one after the other and the staining fluid may be economized. For decoloration, absolute alcohol containing a small amount of hydrochloric acid is preferable. This alcoholic decolorizing agent is effective enough to decolorize a thinly smeared preparation and will not destroy the protoplasm of the leucocytes. By this method a beautiful preparation may be made. This decolorizing fluid, by the way, may be also used for the examination of the sputum. It consists of concentrated hydrochloric acid, 2 drops, in absolute alcohol, 100 c.c.

If the smeared preparation is thin enough, it is decolorized in 2 or 3 seconds. If the preparation is allowed to be acted upon too long by this agent, the staining of the protoplasm of the leucocytes will be affected.

Restaining is made with the mixture of methylene blue and borax. The mixture is prepared as follows: Methylene blue, 1.0 gm.; borax, 2.5 gm.; distilled water, 100.0 c.c. The ingredients are thoroughly mixed and dissolved and the mixture is allowed to stand at room temperature for more than 3 months. It will then take on a purplish color, when it is ready for use. Before use, it is diluted 10 to 20 times with distilled water. This fluid may be used in place of Löffler's solution of methylene-blue for bacteriological purposes. For the staining of cells the Löffler solution is even better than the other. Therefore, this may be best employed for the microscopical examination of sputum and pus. It requires only one minute to attain the good result.

B. Dysentery Bacillus: The smear is dried in the air and fixed over the flame. It is then treated with a mixture of absolute alcohol, 10.0 c.c., and 5 per cent. solution of carbolic acid, 90.0 c.c., and heated for several seconds in order to decolorize the hemoglobin. The decolorizing fluid is then decanted off and the alcoholic solution of hydrochloric acid is poured over the preparation. Hemoglobin will be decolorized at once and the smear will become transparent, hardly recognizable to the naked eye. It is then washed with water and stained with the mixture of methylene blue and borax, which is allowed to act for a minute.

If either of the above mentioned decolorizing agents is allowed to act upon the smear too long, the leucocytes and the bacilli will be stained poorly. If properly treated by this method, the erythrocytes are decolorized and the margin of the protoplasm of the leucocytes is clearly shown, so that the calculation will be very easy.

C. Bacilli of the Typhoid Group: These may be stained in the same way as the dysentery bacillus. Owing to the fact, however, that this group of the bacilli is easily affected by the blood plasma and sometimes is hardly stained by the mixture of methylene blue and borax, it would be preferable to employ either Giemsa's or Otani's solution. The fixing is made by immersing the smear for one half-hour in absolute alcohol or for 15 minutes in pure methyl alcohol. It is then put into a well washed Petri dish, which is filled with 15 to 20 c.c. of distilled water containing 15 to 20 drops of Giemsa's solution or Otani's azur-eosin solution. Having been acted upon for 10 minutes, it is taken out of the dish, washed with water, dried, and closed. The optimum staining gives a purplish color to the nuclei of the leucocytes. If this is attained, the protoplasm of the neutral polynuclear leucocytes appears pink, while the bacilli in them take a dark blue color, as appears in the plate. If the staining fluid is allowed to act too long, the granules of the leucocytes will appear clearly, while the bacilli will take a purplish color, and therefore the distinction between the bacilli and the granules will be very difficult. By this method, dysentery bacilli will be shown very beautifully.

V. *Calculation.*—The degree of phagocytosis was formerly determined by calculating the number of the phagocyted bacilli. Further experiments proved that phagocytosis may be estimated more simply and reliably by taking the percentage of the leucocytes that have phagocyted the bacilli than by the previous method of calculation. The calculation is made of the neutrophile leucocytes, large mononuclear leucocytes, and transition cells. When stained by the mixture of methylene blue and borax, the nuclei of the cells take a pale purplish blue color, the protoplasm of the neutrophile leucocytes a pale blue color, and the protoplasm of the eosinophile cells green. In the last-mentioned cells bubble-like granules, which strongly refract light, are often seen. The protoplasm of the lymph cells and mononuclear cells is stained comparatively dark bluish and the bacilli dark blue. Erythrocytes are decolorized by the mixture of alcohol and dilute carbolic acid and by the mixture of hydrochloric acid and alcohol. They are seen as pale white bodies. The staining by Otani's azur-eosin is quite similar to that obtained by the Giemsa solution. It would seem very difficult to ascertain whether the bacilli are really phagocyted by the leucocytes or merely attached to the surface of the leucocytes. In the practical examination, however, no such difficulties will be encountered, as we have repeatedly stated that the blood plasma which has given a negative result with tubercle bacilli, typhoid bacilli, and dysentery bacilli, will always give a negative result, however often we repeat the same test. Sometimes, bacilli are seen to be adherent to the outer surface of the leucocytes, in which case they are excluded from our calculation. In any case, any leucocytes that have been broken up or seem doubtful as to their participation in the phagocytosis should never be taken into calculation. Thus one hundred leucocytes are observed and the phagocytosis is estimated directly by the percentage of the phagocyted leucocytes. The ultimate judgment is given according to the following:

Less than 10 per cent., negative.

More than 11 per cent. and less than 20 per cent., doubtful.

More than 21 per cent. and less than 30 per cent., weakly positive.

More than 31 per cent. and less than 40 per cent., moderately positive.

More than 41 per cent., strongly positive.

Judged by the above standard, phagocytosis of the citrated normal blood plasma will give almost always a negative result with typhoid and dysentery bacilli, and very seldom a doubtful result. On the contrary, the citrated blood plasma of patients having the infection of either of these bacilli, or that of vaccinated persons or of those who have personally suffered from infection with either of these bacilli will give a positive result in the presence of that particular species of bacteria from which they had suffered. Against tubercle bacilli, the citrated normal blood plasma will give sometimes a weakly positive result, in many cases a doubtful result, and in a small number a negative result. These results may be viewed in the light of the fact that there are many apparently healthy persons who have been affected by tubercle bacilli without developing any noteworthy clinical manifestations. Of these apparently healthy persons, those who give a positive von Pirquet reaction show generally a higher degree of phagocytosis. It must be noted, however, that the phagocytosis and von Pirquet tests by no means always run parallel, for those in whom the von Pirquet is weakly positive may show a comparatively negative result in the phagocytosis test. The tuberculous blood plasma gives almost always a moderately or strongly positive phagocytosis and rarely a weakly positive result. On the other hand, the patient who has a negative von Pirquet may give a positive result in the phagocytosis test. Details of the experiments will be dealt with later.

THE CANCER PROBLEM.

A CONTRIBUTION TOWARD ITS SOLUTION.

By ELMER H. KING, M.D.,

PORTLAND, ME.

During many years of pathological work, there has been constantly in my mind a belief that some microorganism would be found to be the cause of cancer.

In 1912, I found an organism not entirely new to me, nor, perhaps, to other observers; but I found it in a new connection. Following this clue, I was able, in the next three years, to observe its complete cycle in the living tissue.

This organism is constantly found in sections of carcinomata, when they are properly prepared; is constantly present in the urine; and, from a lesser number of observations of the blood of cancer patients, appears to be constantly present there. The organism has been recovered from carcinomata in pure culture; has been cultivated upon media in pure culture; and inoculations of this culture into human beings have resulted in tumors, sections of which showed the characteristics of carcinomata. This organism has been recovered in pure culture from the tumors which followed inoculations.

The organism is definitely a fungus, whose morphology, in consequence of its dual sexual-asexual cycle, is extremely varied.

The sexual cycle, observed thus far only in carcinomata, and in the body excreta and blood of those suffering from carcinomata, presents three forms for consideration: First, the sex elements, hereinafter called the gametes; second, the conjugate form, later referred to as zygocyte, resulting from the conjugation of two gametes; and third, the product of development of the zygocyte, the mature segmented spore sac, later called the mother spore.

The gametes are approximately two microns in size. They are nearly spherical and highly refractile. They present a central ruby red pigment spot which, in function, seems to correspond to the nucleus of germ cells. They present also a cytoplasm of green color.

The zygocyte is distinguishable by fusion of the nuclear material of the two gametes within a common cytoplasm, the long axes of the nuclei of the component gametes lying parallel. Later, during the development of the zygocyte there occurs dispersion of the red nuclear material throughout the growing cell.

Segmentation, resulting upon the maturation of the zygocyte yields the mother spore. This cell, before the discharge of the contained gametes, is fairly constant in size. The limits thus far observed are six microns and ten microns. The discharge of the gametes occurs through a trapdoor opening in the enclosing cell membrane of the mother spore. The gametes leave the mother spore under their own power, for they are motile. They lose their motility after conjugation, and very soon, also, if they do not conjugate. Conjugation of gametes within the mother spore sac has not been observed.

The organism, upon media, exhibits purely its asexual cycle. Its growth is accomplished by a process resembling the budding of yeast. There are two forms in this cycle: A spherical body, approximately three microns in size, observed upon media and in carcinomata; and a rod-shaped body approximately one micron by four microns occurring in chains of not more than four individuals, found chiefly in carcinomata.

All forms except the rod-shaped form have been observed intracellular.

763 Congress Street.

Source of African Yellow Fever.—In French West Africa in 1912 cases of yellow fever were imported over the adjacent British frontier, the disease having reappeared in that territory in 1911. The disease spread through Senegal by wagon routes, whereby the offending stegomyias were carried throughout the province. The old view that West Africa is normally infected from the Western Hemisphere was again agitated but not only were there no suspected vessels to accuse but quarantine in the African ports is very strict and leaves nothing to be desired. No passenger landed from an American boat has ever developed the disease at a later period. Dakar, the principal port, was evidently infected from within the colony. The recrudescence of the disease is doubtless due to the fact that immune negro children serve as carriers. In addition these children show morbidity which is in all likelihood due to the yellow fever germ. Negro racial immunity is largely an acquired immunity due to mild infection in childhood.—*Office International d'Hygiène Publique.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, March 13, 1920.

ANNUAL REPORT OF THE SURGEON GENERAL OF THE NAVY.

WHEN one recalls the marvel of the transport system, by which our fighting forces were landed quickly and safely on allied shores, our wounded brought home with comfort and care never known in the history of the transport of the wounded in war, and our well troops, their work ended, returned to our own shores, one reads with increased pride and interest the statement of the Surgeon General of the United States Navy, in his annual report for the fiscal year 1919, that, "The policy of the bureau has continued to be one of strict attention to its main concern—the health of the Navy and of the several million men of the Army committed to the care of the Navy while on the deep." And in these days of investigations, Congressional and otherwise, when virtually everything and everybody—including the investigators—are being investigated or criticized, it is heartening to read: "Furthermore, this bureau and all its accredited representatives have carefully refrained from any expression of opinion on the performance of duty and the management of affairs outside of its domain where errors of judgment and execution have sometimes led to criticism or comment on matters beyond our control."

The splendid work of the Navy during the turbulent days of demobilization following the armistice is realized when one reads the actual figures involved. The transport service was increased from thirty-eight vessels to approximately one hundred and twenty-nine vessels. Many of these ships were equipped solely for the transportation of healthy troops and were provided with adequate sick bays for that type of personnel, but not infrequently both sick and wounded were received by these troopships. In consequence, the Bureau of Medicine and Surgery found it essential to maintain on board each vessel a medical equipment adequate to meet exceptional demands, so that the total commissioned personnel of the medical corps required for this service was over five hundred men. Their accomplishment is well known by the fact that at the end of the fiscal year, June 30, 1919, 1.235,933 troops had been returned by this service from Europe subsequent to the signing of the armistice. Of this number there were 111,522 transported as sick and wounded of the Army, Navy, and Marine Corps.

In addition to enabling the Navy and the rest of the world to realize just how admirably this department could rise to almost unthinkable emergencies, the war at the same time served in this instance, as in many others, to reveal certain deficiencies. Thus we find an acknowledgment of the fact that the Naval Reserve Force afforded specialists of high attainments in surgery, internal medicine, ophthalmology, otology, and laryngology, and that this served to emphasize the shortage of officers of this type in the Regular Establishment. This commendable frankness should call for the cooperation, on the part of those concerned in an active capacity, in providing the educational program in these specialties which the Surgeon General briefly outlines in his report.

It is impossible here to mention in detail the many interesting phases of the work continued or completed during the period covered by the report, to survey the record of diseases and wounds treated, or to summarize the interesting statistics concerning the individual troopships and their cargoes. The report stands as convincing proof that the Bureau of Medicine and Surgery of the United States Navy continued to give "strict attention to its main concern."

ROCKY MOUNTAIN SPOTTED FEVER.

ROCKY MOUNTAIN spotted fever has probably existed in Idaho and Montana for many years, but it failed to attract much attention until about twenty years ago when Wilson and Chowning decided, after a study of the disease, that it was transmitted by a tick, which was later identified as *Dermacentor venustus*, and found the *"Pyroplasma hominis"* which they believed to be the cause of the disease. Later studies failed to confirm the infection as a pyroplasmosis but Ricketts was able to transmit the disease from man to monkeys and guinea pigs and probably saw the organisms which recently have been thought to have been the exciting cause.

Wolbach has recently published (*Jour. Med. Research*, 1919, xli, 1) the results of an exhaustive study of the condition in all of its phases and his report is a model of thoroughness and care. It is naturally impossible to summarize this report in anything approaching a detailed manner and we can here point out only the most striking features. The virus alternates between the ticks and mammals but hereditary transmission in ticks has been demonstrated. Mammalian carriers have not been demonstrated. The disease may be defined as "An acute specific infectious endangiitis, chiefly of the periphreal blood vessels," and the parasite shows this specificity for the peripheral vessels in all experimental animals. The skin lesions are characteristic and icterus and splenomegaly are constant. The disease is very similar to typhus fever and tsutsugamushi disease or Japanese river fever.

The parasite appears in paired lanceolate, slender rod-shaped or very minute rounded forms depending upon the methods used and the material from which it is obtained. Wolbach thinks it represents a new type of parasite and has named it *Dermacentroxenus rickettsi*. Its extreme susceptibility to physical and chemical agents and its staining reactions seem to indicate that it is not bacterial. It is not a filterable virus. He was not able to cultivate it by any means at his command. His arguments in favor of considering it the causative organism of the disease are as follows: "(1.) The constant occurrence of a microorganism of distinctive size and morphology in the lesions characteristic of the disease in man, monkey, rabbit, and guinea-pig. (2.) The constant presence of an identical microorganism exhibiting undoubted evidences of developmental phases in ticks of proved infectivity, and the absence of similar forms in proved noninfective ticks. (3.) The ability to recognize this specific microorganism in the tissues and eggs of infective ticks in the presence of bacteria occasionally present in abundance in ticks of the species concerned."

Should this work be confirmed it not only must be considered as one of the outstanding scientific achievements of the period but will also have a definite and not small economic value. The presence of this disease and its prevalence in certain localities have been of distinct disadvantage commercially. If a large mammal can be found to be susceptible to the disease it may be hoped to produce an immune serum, for a second attack in one individual is unknown. Furthermore the existence of an entire group of hitherto unrecognized microorganisms, if confirmed, will open the way for the discovery of the cause of other infectious diseases whose causative agent is at present unknown.

ETIOLOGY AND TREATMENT OF INFLUENZA.

THE etiology of influenza is still an unsettled question, that is, it is not now definitely believed, as was the case up to the time of the last pandemic, that Pfeiffer's bacillus is the cause, or rather the sole cause. In the discussions on influenza which took place at the Royal Society of Medicine in 1919 and which are published in the Proceedings of that society for 1919, xii, pp. 78-83, Dr. W. E. Carnegie Dickson remarks that with regard to the occurrence of *Bacillus influenzæ* itself, he had had hitherto little doubt that it was the probable primary infective agent concerned in the production of the recent epidemic in England. At any rate, it is one of the organisms most constantly found, and is certainly itself pathogenic. As a rule, his findings practically coincided with the various published official reports. But on one or two points his results differed slightly. In addition to the hemolytic diplostreptococci, which were most frequent, and pneumococci next so, as organisms of secondary infection following, or in many cases coincident with Gram-negative influenza, like bacilli, Dickson would emphasize the comparative frequency of the presence of staphylococci, especially *Staphylococcus aureus*. He found the latter in the cultures of the washed sputum of rather more than 50 per cent. of the cases with pulmonary complications, and in the lungs and pleuræ in about a quarter of the fatal cases, in addition to the usual strepto- and pneumococci and *Bacillus influenzæ* itself. It was also present in ten pleural fluids removed by chest puncture during life, four times in pure culture. He therefore thinks it should be regarded as one of the important organisms of secondary infection, although it has not been included in the official vaccine. Dickson also thinks that Friedlander's bacillus occurred with sufficient frequency to merit inclusion.

It seems then that Dickson, like so many other bacteriologists, is not as sure as formerly that the primary infection of influenza is caused by the Pfeiffer bacillus, and yet, though somewhat doubtful, he still appears to veer rather strongly to the belief that it is. A little further in the paper he refers to the important question of the carrier of the Pfeiffer bacillus and points out that in the numerous examinations he made, one of the most noticeable features was the frequent occurrence of small Gram-negative influenza-like bacilli in many of the cases of chronic bronchitis in which, clinically, no suspicion of the presence of influenza had arisen. They grow upon blood media and conform culturally and morphologically to Pfeiffer's bacillus, and he is convinced that they constitute the reservoir of infection in the country.

As for the vaccine treatment Dickson seems to have had fair success with it prophylactically, although, of course, the prophylactic effects of a vaccine are difficult to estimate, and had encouraging results therapeutically. The approximate composition of the mixed vaccine, taking the whole as "twenty" was streptococci five parts; staphylococci, five parts; pneumococci, three parts; minute Gram-negative influenza-like bacilli, three parts; Friedlander's bacilli, two parts and other organisms (*Micrococcus catarrhalis*, etc.), two parts. The results of treatment by the vaccine, according to Dickson's clinical colleagues, were beneficial. In most cases the disease was apparently shortened and the occurrence of complications prevented.

With regard to the vaccine treatment of purulent bronchitis, bronchopneumonia, pleurisy, empyema, and so on, Dickson at first advised small doses given at intervals of three to four days, according to the nature and severity of the case. Later on he advised larger doses, and the intervals were cautiously decreased again. While there was not a sufficient number of cases upon which to base a scientific opinion, his clinical colleagues had a considerable amount of success in such cases as were not actually moribund.

From his own experience Dickson speaks well of the prophylactic effects of the vaccine. He has

given the vaccine prophylactically to about 500 persons, and so far as he could ascertain, only two of these developed anything resembling influenza.

Perhaps the most instructive part of Dickson's paper is that which relates to the question of influenza carriers. This point is well worthy of the attention of public health authorities in dealing with the question of preventing epidemics of influenza.

Congenital Absence of the Nails.

Congenital anomalies of the nails are extremely rare. Their complete absence, anonychia, in particular, is of all the ungual malformations the least frequent. Complete and total anonychia of all the fingers or toes is very exceptional. This congenital defect, when it exists, may be the only one presented by the patient, but it is generally associated with other anomalies or defective conformation usually classified under the heading of stigmata of degeneration. This defect, therefore, is itself a physical stigma of degeneration. In some instances anonychia is a familiar malformation; it may be hereditary, or without being hereditary it may occur in several members of the same family. The pathogenesis of this congenital defect, like that of the majority of malformations, is obscure. All that can be said is that it is the result of an arrested development of the nails occurring at about the third or fourth month of gestation. In point of fact it is during the third month of intrauterine life that the primary matrix of the nail becomes constituted in the embryo and it does not become covered by the ungual limbus until a month later. This interpretation well fits the description of cases of anonychia which show that there invariably exists, in the place of the absent nail a normal ungual matrix, usually well developed and distinct in outline. It is likewise in accord with the results derived from pathological examination which show that the cells of the epidermic stratum lining the surface of the ungual matrix have undergone an evolution toward ordinary epidermic keratinization and not toward the ungual type of keratinization. Now, this is a transformation which commences to show itself at the very beginning of the fourth month of intrauterine life. But given the actual state of the question, the cause of this arrest of development is absolutely unknown and the rather incomplete data which we possess on the antecedents of subjects presenting anonychia are not sufficient evidence to show that syphilitic or tuberculous infection or alcoholism was present in the parents.

Symbiotes.

Castellanos in *Vida Nueva* for November, 1919, xi, 11 refers to studies by a Mexican scientist, Herrera, on the minute bodies later termed by Portier symbiotes. Herrera had styled the organism *Micrococcus brownianus*, and regarded it as a biological scavenger and, far from being a friendly parasite, as an enemy to man. The *Micrococcus brownianus* of the Mexican biologist exists in the interior of the body cellules. Its resistance to destructive agencies is incredible. Herrera first published a paper on the subject more than eight years ago and is clearly entitled to priority. The research thus inaugurated in Mexico was later taken up by Villazon, of La Paz, Bolivia, and numerous other Latin Americans, and the *Micrococcus brownianus* seems likely to bring about concerted action by the Spanish-American scientists of the New World with the aim of securing to any pioneer work done by members of this fraternity credit for priority. Some of Herrera's colleagues appear to have regarded his discovery with ridicule until endorsed by men like Portier and Galippe before the French Academy of Sciences. The author seems unaware of the fact that Portier's discovery has in turn been ridiculed by some of his peers, who explain the alleged symbiotes in still another way regarding them as ordinary saprophytes which have interpenetrated the cells from the outer world. Others have gone beyond Portier and have seen in the symbiotes the structural basis of the vitamines. With such numerous and discordant views it seems too early to speak of priority, but the subject is one of much interest and Herrera appears to have been the first to get into print of recent years, although the same bodies were evidently seen by biologists many decades ago.

News of the Week.

Relief of Disabled Ex-Service Men and Women.—The Government's position with reference to treatment for former soldiers, sailors, and marines who are in need of medical attention because of war injuries or disease contracted in the service, is set forth in a pamphlet, "Relief to Disabled Men through the United States Public Health Service," published by the Office of the Assistant to the Secretary of War. Under Public Act 326, the United States Public Health Service will furnish relief to any honorably discharged soldier, sailor, or marine, or Army or Navy nurse (male or female) who was discharged on or after October 6, 1917, and becomes disabled or ill on account of illness or injury incurred previous to discharge from service, and not due to misconduct. Copies of the pamphlet explaining the law may be secured without charge by any physician on application to the Office of the Assistant to the Secretary of War, Service and Information Branch, Council of National Defense Building, Washington, D. C. It has already been distributed to all Army and Navy hospitals, State and city health officers, and United States Public Health Service Stations.

Schick Test in Schools.—Dr. William H. Park, Director of the Bureau of Laboratories of the Health Department, New York City, has announced that the Schick test for diphtheria will soon be extended to one hundred schools in this city. Successful application of the test was made in twenty schools last year.

"Talcum Shops" Whiskey Stores.—"Talcum powder druggists" are under investigation in Chicago. A window display of a few boxes of talcum powder and a store filled with whisky "for medicinal purposes" constitute the stock in trade of these denizens of the Windy City. The investigation followed the arrest of two doctors, one of

whom admitted that he had written from one hundred to two hundred prescriptions for whisky daily, collecting a fee of from one to seven dollars per prescription, depending upon the patients' ability to "cough."

Drug Addicts' Clinic Closed.—The New York City Health Department has closed the Worth Street clinic for drug addicts, which has been maintained since 1910. At first as many as 3000 addicts a day came to the clinic, but the number dropped to about 150 a day. This fall in attendance is said to be due to the fact that physicians have taken up the legitimate treatment of such patients. Those who have been attending the clinic will be treated at the hospital on North Brothers Island. There is now plenty of room in the Riverside Hospital for the treatment of addicts, and Health Commissioner Copeland said yesterday that the city was able to treat all applicants. The department will maintain its bureau for the registration of addicts.

Middle Section of "Trilogical" Society Meets.—The annual meeting of the Middle Section of the American Laryngological, Rhinological and Otological Society was held in Cincinnati, Ohio, February 21.

High Price of Materials Blamed for High Fees.—The news comes that the raise in rates recently announced by members of the West Side Physicians' Business League of Dayton, Ohio, may be charged to the high cost of bandages and other physicians' materials. The Montgomery County Medical Society, it seems, has not sanctioned the new rates, but they have the unanimous approval of the Dayton physicians.

Camp May Get Medical School.—Camp Zachary Taylor, Louisville, Ky., has been proposed as location for the Medical Department Field Service School. If selected, all Medical Department recruits will be sent there before being assigned to their permanent organizations. Camp Taylor, it is stated, meets all the requirements of such an institution.

Shortage of Doctors in Virginia.—Senator Andrews recently offered a joint resolution calling for an investigation of the alleged shortage of doctors in Virginia. According to the resolution the inhabitants of many parts of the State are unable to secure prompt medical aid. The State Board of Medical Examiners is directed to make an investigation and to make recommendations regarding the situation at the next session of the Legislature.

Post-Graduate Drive.—The New York Post-Graduate Medical School and Hospital has announced the intention of launching a campaign to raise $2,000,000 to meet the increased responsibilities placed upon it in consequence of the elimination, by the war, of European medical centers. Registrations for the Post-Graduate seminars this year, according to a statement recently issued by Dr. Frederick E. Sondern, president of the institution, exceeds all records of the school in its thirty-six years of work. The enrollment for 1919-20 is 1692, as compared with 877 for the previous year.

Hospitals for Negroes in the South.—The Interchurch World Movement proposes to build hospitals under church control exclusively for negroes in nine Southern States, at a cost of $3,100,000. Hospitals for negroes in Jacksonville, Fla., Nashville, Tenn., and New Orleans, La., will be supported by the movement, and at least one general hospital is planned for Alabama, Georgia, Kentucky, Mississippi, Missouri, North and South Carolina, Texas and Virginia.

Special Commission to Study Health Insurance Recommended.—In a letter to the New York State Legislature Warren S. Stone, Chairman of the Social Insurance Committee of the National Civic Federation and Grand Chief of the International Brotherhood of Locomotive Engineers, has recommended delay in legislation establishing a State system of health insurance until a special commission can make a study and devise a constructive plan. Similar letters have been sent to the Legislatures of Massachusetts, Rhode Island, New Jersey, and Virginia, in which States legislation of this character is contemplated.

Mt. Sinai Hospital Annexes.—Mt. Sinai Hospital, New York City, is to be enlarged by the erection of two new buildings to cost $3,250,000. One of the buildings, which are to be commenced in the Spring, will be a private pavilion containing 130 rooms. The other will be a children's building, the capacity of which will be 100. An auditorium building also will be erected for use by the hospital, the Department of Health, Columbia and New York Universities, and various medical bodies.

Nursing Drive by Henry Street Settlement.—A campaign to raise $1,000,000 to extend the visiting nurse service of the Henry Street Settlement, New York City, has been planned for March 15 to 22.

Aid for French Hospital.—An endowment of 4,946,000 francs for twenty-four beds in the free wards of the New American Hospital at Neuilly, France, has been made by Mrs. Robert Bacon, widow of Colonel Robert Bacon, formerly American Ambassador to France. The endowment is given in memory of Colonel Bacon. Mrs. Bacon's gift brings the hospital's total yearly revenue from endowments to 344,900 francs. The amount required to operate the hospital is 438,000 francs. The amount necessary for the proposed building is 6,750,000 francs, of which 750,000 francs have been transferred by Henry P. Davison, this being the remainder of one of the war funds of which he was Chairman, 250,000 francs have been given by Mr. and Mrs. George A. Kessler, and 85,000 francs have been subscribed.

Vienna Vital Statistics.—From February 8 to 14 there were 1032 deaths, mostly of children, and eight births in Vienna.

The New York Radium Institute announces the appointment as Associate Director of Dr. Chester Ford Duryea. Dr. Duryea has been associated with Dr. C. Everett Field in laboratory work since 1913 and recently returned from France and England where he had opportunity of observing the methods there advocated in radium therapy.

Verdict Against Medical College.—The Massachusetts Superior Court, according to advices from Boston, has awarded a verdict of $9,000

against the College of Physicians and Surgeons of that city for the "conscious sufferings and death" of a patient treated for tonsillitis. The physician who had prescribed for the patient was fined $501. The suit was brought by the administrator of the estate of the deceased. It was alleged that the patient, a woman, died in 1917, a few days after the treatment; that after death traces of mercurial poisoning were found, and that this resulted from the doses administered by the physician.

League of Red Cross Societies Meets.—The first general council of the League of Red Cross Societies opened in Geneva, Switzerland, March 2. with representatives from twenty-seven nations.

The Western Electro-Therapeutic Association will hold its annual meeting in Kansas City, Mo., May 27-28.

Nurses Strike. — The twenty-three student nurses at Birchmont Hospital, Omaha, Neb., went on strike recently, claiming they were not receiving the full scientific courses guaranteed them on entering the hospital. All patients in the institution at the time were removed to other hospitals.

Women Fellows of the American College of Physicians. — During the recent meeting of the American College of Physicians, held in Chicago in conjunction with the Congress on Internal Medicine, Dr. Anna Weld of Rockford, Ill., and Professor Leila Andrews of the University of Oklahoma, were admitted to membership, the first women to be made fellows of this body. Both physicians have won recognition through work in pediatrics.

Dr. Charles G. Hewitt of Ottawa, Canada, Dominion Entomologist and Consulting Zoologist, died of pneumonia March 1, in his thirty-fifth year. Dr. Hewitt was a frequent contributor to the literature of zoology and entomology. He helped in drafting the treaty between Canada and this country for the protection of migratory birds.

Dr. Hideyo Noguchi, formerly engaged in research work with the Rockefeller Institute, New York City, has recently established laboratories in Yucatan for the purpose of studying yellow fever. He has been made an honorary member of the Mexican Academy of Medicine.

Dr. Daniel S. Dougherty has removed his office to 111 West Eighty-fifth Street, New York City.

Dr. J. G. Pace of Lincoln, Neb., has been appointed to succeed the late Dr. J. L. Rutledge as superintendent of the Modern Woodmen Sanitarium at Colorado Springs, Colo.

Charitable Bequests.—Under the will of the late Miss Elizabeth Dorrance Bugbee of Providence, R. I., the sum of $6,000 is left to the Rhode Island Hospital to establish a free bed in memory of the testator's father and mother, and the residue of her estate is left to the same institution to be used for the sole benefit of the children's ward.

Medical Society Elections. — The WESTERLY (RHODE ISLAND) PHYSICIANS' ASSOCIATION, at its meeting in February, elected the following officers: *President,* Dr. J. Devere Barber; *Vice-President,* Dr. Samuel C. Webster; *Secretary,* William A. Hillard; *Treasurer,* John Champlin; *Censor,* Frank C. Pagan.

Obituary Notes.—Dr. W. W. HORTON of Unionville, Conn., formerly of Bristol, died February 19, at the age of 65. He was graduated from New York University Medical College in 1879.

Dr. CHARLES ZUPPANN of Ballwin, Mo., died on February 15, at the age of 68. He was graduated from Rush Medical College, Chicago, in 1877, and had practised in St. Louis County for thirty-seven years. His death was due to cardiac affection following influenza.

Dr. JOSEPH P. MURPHY of Boston, Mass., died from bronchopneumonia at the Peter Bent Brigham Hospital on February 18, at the age of 58. He was graduated from the Medical School of Harvard University in 1884.

Dr. JOHN VAN DER POEL of New York City died February 22, at the age of 62. He was graduated from the College of Physicians and Surgeons, New York City, in 1881, specializing in urology. He had held various hospital and teaching appointments, and during the war was a member of the staff of the hospital at Château Annel, near Compiègne.

Dr. JOSE M. FERRER of New York City died suddenly February 23, at the age of 63. He was graduated from the College of Physicians and Surgeons in 1879, and was visiting physician to the French and St. Vincent's Hospitals. He was a member of the New York Academy of Medicine, the American Medical Association, and various other bodies.

Dr. FRANK M. BRUNDAGE of Conyngham, Pa., died at the age of 60. He was graduated from Jefferson Medical College in 1874. Dr. Brundage was United States Consul at Aix-la-Chapelle, Germany, for eight years.

Dr. G. A. SENIGAGLIA of Nyack, N. Y., died February 27, at the age of 31. He was graduated from Cornell University Medical College in 1909.

Dr. EDWARD D. HALL of Meriden, Conn., died of pneumonia February 19, at the age of 69. He was graduated from the Medical School of Harvard University in 1873. He was a member of the American Medical Association.

Dr. G. C. RAYNOLDS, pioneer medical missionary in Armenia, died at Berkeley, Cal., recently, at the age of 82. After the Civil War Dr. Raynolds left for Turkey, and for forty-seven years he carried on his missionary work in the city of Van. He and his wife survived numerous Turkish and Kurdish massacres. In 1913 he returned to this country, for the first time since 1869, to get funds to establish a college at Van. On account of the war he could not return until 1915. He remained with the Armenians until the autumn of 1919, when he returned to this country.

Dr. E. D. SEAMAN of Los Angeles, Cal., died February 20. He was born in Ithaca, N. Y., in 1855, and was graduated from the College of Physicians and Surgeons, New York City, in 1884. He had practised in Los Angeles for thirty-five years, and was a member of the American Medical Association and State and local societies.

Dr. LA FAYETTE LEWIS of Wilbur, Wash., died February 21, at the age of 74. He was born in Tennessee in 1845, and had practised in Wilbur and vicinity since 1885.

Dr. PHILIPS COOMBS KNAPP of Boston, Mass., died, after a long illness, February 24, at the age of 62. He was graduated from the Medical School

of Harvard University in 1883, specializing in neuropsychiatry. He had been consulting physician for the Massachusetts State Hospital for the Insane since 1895, and was a trustee of the Boston Insane Hospital from 1897 to 1902. He had held various other hospital appointments, and was a member of the American Neurological Association, the American Medical Association, and various other societies in this country and abroad.

Dr. JOHN C. MCGINNIS of Martins Ferry, W. Va., died in Cincinnati, February 22, at the age of 42. He was graduated from the Cincinnati College of Medicine and Surgery, and served as captain in the Medical Reserve Corps during the war.

Dr. WILLIAM A. SMITH of Springfield, Ohio, died of cardiac disease February 25, at the age of 68. He was graduated from Bellevue Hospital Medical School in 1883. He was a member of the American Medical Association.

Dr. THOMAS AMORY DE BLOIS of Boston, Mass., died February 27. He was born in Columbus, Ga., in 1848, and was graduated from Dartmouth Medical School, in 1878, specializing in otolaryngology. He was a member of the American Laryngological Association.

Dr. EDWARD GERRY TUTTLE of New York City died of pneumonia, February 29, at the age of 69. He was graduated from the New York Homeopathic Medical College and Flower Hospital in 1889, and was professor of gynecology in that institution. He was a Fellow of the American College of Surgeons and of the New York Academy of Pathological Science.

Dr. VER NOOY WAYLAND WEED of Brooklyn, N. Y., died of cerebral hemorrhage in the Neurological Institute, New York City, February 26, in his forty-second year. He was graduated from the College of Physicians and Surgeons in 1900. He was associate surgeon of the Bushwick, Jamaica, and Swedish Hospitals, and a member of the staff of the Consumptives' Home of Brooklyn. Dr. Weed was a member of the American Medical Association, the Medical Society of the County of Kings, the New York Pathological Society, and other organizations.

Dr. MOSES ZELLER of New York City died of encephalitis lethargica at Lincoln Hospital and Home, February 28, at the age of 27. He was graduated from Fordham Medical College in 1918, and was house physician in the Lincoln Hospital and Home at the time of his death. He contracted the disease while attending two patients who were suffering from the sleeping sickness.

Correspondence.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, February 20, 1920.

Meeting of the Consultative Council of the Ministry of Health.—The Consultative Council on General Health Questions, the establishment and composition of which under the Ministry of Health Act have been described in previous letters held its first meeting on February 4, 1920. The Minister of Health, Dr. Christopher Addison, who was accompanied by Viscount Astor, Parliamentary Secretary to the Ministry, presided, and asked the Council to put before him a statement of the main defects in existing provisions for safeguarding the health of the people, and to suggest remedies from the standpoint of persons who as members of the general public will be affected by the health service supervised by the Ministry. The members of the Council have been appointed with this special object in view. An interesting feature of the composition of the Council and a significant sign of the times is that women form a majority of the membership. It may be said that women have shown themselves particularly well fitted for public health work, and perhaps the greater number of them who enter the medical profession will take up the work. So far, however, as the Council on General Health Questions is concerned the numerous women members are not of the medical profession, but have been chosen for their knowledge of industrial conditions both urban and rural.

Medical Men and the Insurance Act.—British medical men are not satisfied with the amended Insurance Act, except a few, and have taken recently every opportunity to voice their grievances. A conference covered by the British Federation of Medical and Allied Societies was held a few weeks ago at Steinway Hall to consider the regulations for 1920 which the Minister of Health has proposed to issue with respect to the administration of the National Health Insurance medical benefit. Sir Malcolm Morris who presided said that the present scheme of insurance was not the best that could be done and it was not too late to appoint a committee or Royal Commission to give something better to the public whose interests were those of the medical profession. Dr. Stancombe said that after some years' experience they were in a position whole-heartedly to condemn the national insurance system which has been greatly injured by the want of auxiliary services such as nurses and consultants. The politicians of this country had not yet grasped the value of national health, and something better was expected from the Ministry of Health than the pettifogging regulations they had brought forward. The panel practitioner to-day felt more and more that he was a bureaucratic slave. There should be a coordinated medical service under the Ministry of Health, although the time was not ripe for imposing either on the country or the profession a full-time medical service. The new service should have local autonomy under bodies known as medical guilds or local health authorities. It is the rules and regulations even more perhaps than what they consider the inadequate rate of remuneration that has set a considerable proportion of the profession against the act. It is obvious that rules and regulations are necessary in any public service, but they should be drawn up so as not to interfere with the conscientious work of an honest man. Bureaucratic methods are antagonistic to the instincts and traditions of English-speaking people who are above all an individualistic race in direct contradistinction to the Germans who are the bureaucratic race of the world. Bureaucratic methods destroy individualism and a multitude of rules

and regulations savor too much of Teutonic origin. Panel practitioners should be allowed to discharge their duties toward their patients with as little irksome supervision as possible. It is said that Dr. Addison admits this at the conference referred to above. Dr. G. Dill drew attention to another point in or defect of the insurance act and that was its absolute dependence on the voluntary hospitals. He said that without the aid of the voluntary hospitals the act would be unworkable. The new regulations offered no improvement. There was no provision for bacteriological diagnosis or for *x*-ray examination. The doctor should earn his living by keeping the nation well not by profiting by its infirmities. Let them say to the Prime Minister: "We, the medical profession, will assure the health of the nation, and we will draw up a scheme if we are assured a sufficient premium." The point brought forward by Dr. Dill that the medical provisions of the insurance act would have been unworkable without the help of the voluntary hospitals is one well taken. Not only that but it is partly on account of the extra pressure placed on these institutions by the insurance work that they are in the parlous condition they are at present. There is no doubt that a Ministry of Health was needed in Great Britain and there is also no doubt that it has a "hard road to hoe" and that consequently criticism should be unbiased and fair. After all it is the health of the nation that is the chief concern, and it is true that owing to untoward conditions caused by the war the progress of the Ministry is considerably impeded. The Ministry must be given credit for the best of intentions and should not be hampered by indiscreet objections on the part of the medical profession. At the same time, it must be recognized by the Ministry as doubtless it is recognized that not to treat the profession generously and justly would indeed be unwise policy. Whether panel practice is an advance or a retrograde movement cannot be stated offhand. The only thing that can be said is that experience of it in Great Britain so far has not made it popular with the profession nor, perhaps, does it seem greatly in favor with the general public.

Sanatorium Treatment of Tuberculosis.—The sanatorium treatment of tuberculosis has been subjected during the past few years to a good deal of destructive criticism. In fact, it has been demonstrated that the sanatorium by itself is comparatively useless, and that in order to obtain the best results from treatment, it must be coordinated and combined. Dispensaries, hospitals, sanatoriums and colonies are all factors of importance, if employed in the proper way and in conjunction. That the sanatorium alone is of little avail, some evidence which has come to hand recently appears to prove conclusively. Figures relating to tuberculosis presented to the Essex Insurance Committee at their monthly meeting at the end of January, 1920, disclose the startling facts that of 619 people who came up for sanatorium treatment during 1914, 319 have died since. In 146 cases the patients have improved under treatment, in 111 cases the disease has been arrested, 13 are stationary, 4 are worse and 29 are doubtful. Commenting on these facts, Dr. Butler Harris said the figures pointed to one moral, the sanatorium benefit was not the whole story. Until they tackled the housing and general social problems, and the important question of after care of the patient, they would not get very far toward solving the problem. Two conferences, he said, had been held recently with a view to securing a closer cooperation between the general practitioners and the tuberculosis officers, and it was hoped shortly to bring out a plan which would help the doctors, the tuberculosis patients, and everybody concerned with the work of treatment—and the amelioration of the disease.

The Condition of the Hospitals in Great Britain. Nearly every hospital in this country has been sending out appeals for financial aid during the past few months. In the East End of London, that conglomeration of mean streets and squalid houses, which contain more than 2,000,000 of the poorest, the hospitals are in desperate straits. For example, the Special Appeal Committee of the Queen's Hospital for Children, Hackney, E., points out that the hospital will be compelled to close two wards containing 62 beds within three months unless funds can be obtained to pay off the deficit. The closing of the wards would deprive 800 invalids from the poorest parts of London of medical and surgical treatment. The institution is over £10,000 in debt, and an additional £5,000 per annum is required if the hospital is to be kept at its pre-war standard. At least 40,000 mothers take their children thither in sickness and accident during the year, the attendance in the casualty and out-patients' department numbering over 10,000 and the demands on the 170 beds are always most pressing. This is quoted merely as a typical instance of the condition into which the hospitals of Great Britain have fallen.

The People's League of Health.—The League was launched a short time ago. The founder of the movement and organizer is the well-known actress, Miss Olga Nethersole, and the avowed objects of the League are to inquire into the social problems which necessarily govern the health of the nation and to improve the social and economic conditions of the masses; to disseminate knowledge of health; and by lectures to be delivered by members of the medical profession, to afford information on the contributory causes of moral and physical diseases. A national campaign has been outlined, not to compete with any existing organization, but rather to increase the forces necessary to improve the health of the nation. Among the speakers at the first meeting was Dr. Eric Pritchard who said in part that the falling birth rate was not due to any natural law. It had been supposed that as a nation became more civilized and more intellectual the birth rate naturally declined. But he was informed that the decrease in the birth rate was not due to any great excess of intellectuality on the part of the nation; it was rather due to the fact that a considerable amount of selfishness prevailed amongst those classes who could afford to have larger families than they had. It seemed to him exceedingly disquieting that the recruiting of our man power at the present time came very largely from those sources in which the environment for the up-bringing of children was

the least favorable for having a sound and healthy nation. The man power of the country was now recruited from those industrial centers where the conditions for children were the worst possible. If they wished to improve the physique of the nation as a whole they must improve the physique of the children. They must improve the mothers, the children, the infants and the homes.

Disabled Men's Training.—The Minister of Pensions, will on February 20, formally open the Lancashire Convalescent Center, which has been established by the Ministry of Pensions at Blackpool. In the course of the next few months similar institutions will be opened at Epsom, Birmingham, Plymouth, Edinburgh, Buttrills Camp (Wales) and Gormanstown (Ireland) where buildings are being adapted and the necessary equipment installed. The system may be further extended if the need for more accommodation should arise. These large centers, like the smaller institutions hitherto existing in different parts of the country are designed for the benefit of disabled ex-service men, who, while undergoing medical treatment, will be taught the technique of a variety of occupations.

3. The Specific Diagnosis and Treatment of Acute Lobar Pneumonia. Lesley H. Spooner.

2. The Mental Factor in the Chronic Intestinal Invalid.—John Bryant defines the chronic intestinal invalid as an individual who is usually in rather poor health from an intestinal point of view. Many of these individuals, having very little gastric distress, do not associate their poor health with intestinal abnormalities. Having a daily bowel movement, they do not consider that this movement may be one or more days late in arriving. There is often, on the other hand, a clear history of intestinal trouble dating back to childhood, the influence of heredity frequently seeming to be a factor. The degree of poor health is variable. Excessive fatigue, either mental or physical, almost invariably precipitates a train of symptoms, among which intestinal pain and intermittent diarrhea, or constipation, predominate. Accompanying this more purely gastrointestinal display of symptoms is a condition of bodily exhaustion varying in degree according to the length of time for which the particular patient has been under strain. The chronic intestinal invalid is usually "high-strung and excitable"; this mentality is usually heralded by a long, thin, often emaciated and carnivorous type of body. The skin is usually pallid or sallow, and may be so discolored as to suggest Addison's disease. The individual often presents the text-book picture of drop-heart and all the other classic features of visceroptosis. Two case histories are presented, illustrating two distinct types of mental commotion often encountered in the treatment of the chronic intestinal invalid. In one case the mental commotion was due to a summation of general causes; in the other case the mental commotion was due to two specific factors. In both cases relief of the mental commotion proved a very important factor in the recovery of the patient.

4. Thyroidal Constipation. — Spencer G. Strauss states that thyroid therapy for the cure of various states of constipation appears to have been employed in a purely empirical way, with the resulting disastrous effect that the busy practitioner is now likely to use this latest addition to his therapeutic armament as harmfully as he formerly did the common garden variety of cathartic pill. Thyroid extract, the writer holds, however given, is not, nor will it ever be, a constipation remedy; nor can it ever become a cure for constipation as such unless in its administration it corrects a constitutional defect which predisposes the individual to an abnormal metabolic state, which in its manifestations includes a deficient bowel evacuation constipation. One must have regard for the rest of the picture, however, and prescribe thyroid extract only when one feels justified, after a careful physical analysis, that the patient presents a condition of thyroid disbalance. In this connection Strauss calls attention to the theory that the thyroid gland in the human physiology seems to act, not alone by virtue of its own inherent qualities, but by its peculiar ability to activate and coordinate the functions of the other glands of internal secretion, and in this way one may obtain happy results from thyroid therapy. Thyroid extract should be employed only when the thyroid regulation is essentially to blame, as established by careful search for evidence warranting its condemnation. Clinical study shows that various qualitative and quantitative marks are characteristic of thyroid disbalance *per se*. They cannot be proved as yet in the laboratory, but they are valuable nevertheless. The writer indicates the more usual thyroidal marks which, when combined with the so-called constipation, call for thyroid therapy.

3. The Diagnosis of Heart Disease in Young People.—Paul D. White considers that one of the most important lessons that the civilian physician learns from his army experiences is the need of more accurate diagnosis of heart conditions in young people. Since his return to civil life he has noticed a group of cases, particularly in young women, which had been diagnosed as heart disease, sometimes for years, not infrequently as mitral stenosis, which he feels were no more heart disease than were cases of effort syndrome encountered in soldiers during the war. The importance of this matter is obvious. Other conditions besides effort syndrome which, because of the symptomatology, may simulate heart disease are hypothyroidism and infectious diseases. The writer holds that positive evidence of heart disease on physical examination includes any of the following: 1. Definite cardiac enlargement, to be determined, if in doubt, by teleroentgenology, or orthodiography. 2. The presence of diastolic murmur. 3. A systolic murmur at the apex, if very loud, and especially if it masks the first sound, usually means evidence of actual involvement of the mitral valve.

A very loud systolic murmur at the base, with thrill, indicates the presence of stenosis of the pumonary valve or of the aortic valve. 4. The presence of serious arrhythmia, that is, heart-block, or auricular fibrillation, if not the result of digitalis. 5. Congestion of the veins of the neck. 6. Enlargement of the liver. Edema of the feet and legs, or, if a patient is in bed, of the sacral region; ascites and hydrothorax, and edema of the lungs. 7. Cyanosis. The presence of very severe anginal pain is in favor of organic heart disease. The presence of extreme nervousness, tremor, sweating, and other vasomotor phenomena favors the diagnosis of effort syndrome. Occasionally one finds a combination of the two conditions which may give rise to a good deal of difficulty in diagnosis. The writer emphasizes the point that even when the heart is damaged and a diagnosis of slight involvement can be made accurately, the life of the individual should not be too closely restricted, or the patient too much alarmed over the abnormal heart finding. The writer cites a case illustrative of the differential diagnosis between heart disease and effort syndrome.

5. Acute Respiratory Disease Carriers.—Lesley H. Spooner made a study of this subject with regard to the four most important organisms that are etiologic factors of acute respiratory infection, namely, the pneumococcus, *Bacillus diphtheriæ*, the meningococcus, and the streptococcus. From this study the writer holds that the transient healthy carrier is more common than should be expected from the incidence of the specific disease. This transient quality is shown by the disappearance of the organism without treatment. The chronic healthy carrier is rare, except in the case of the "saprophytic pneumococcus" of Cole, in which many of the organisms may be nonpathogenic, and with *Streptococcus hemolyticus*, in which a similar condition may well exist. The potent factors in the spread of these diseases rest in this small group of chronic healthy carriers and the diseased carrier. The latter, during the prodromal stages of disease and convalescence, is of by far the greatest importance. They respond to attempts at disinfection even less satisfactorily than do the chronic healthy carriers.

2. Dental Sepsis in Children: Its Consequences and Treatment.—F. St. J. Steadman considers the effects of dental sepsis in children under two main headings, general and local. The general effects manifest themselves in retardation of growth, pale-faced, and anemic condition, lack of normal luster of the eyes, and a tired and sleepy look. A common result of oral sepsis in children is disorder of the gastrointestinal tract, as evidenced by gastric and abdominal pain, diarrhea of an offensive character, with much undigested food in the motions, marked wasting, fretfulness, night-terrors, loss of appetite, sleeplessness, and pallor of the face. Under local effects the writer includes the adjacent parts to which infection spreads by continuity of tissue. Pharyngitis, tonsilitis, otitis media, and—much more rarely—meningitis and such-like troubles. Infection may pass down the lymphatics to the submaxillary and cervical glands. Steadman takes issue with the view that enlargement of these glands is so common that it is not worth while even examining for them. He holds that normally the submaxillary and cervical glands are not palpable in children, and that if they are, there is sepsis somewhere. Carious teeth frequently produce enlarged glands, as proved by the fact that these glands disappear after the removal of the teeth. Of course, enlarged cervical glands occur at times in children with perfectly clean mouths. In the treatment of dental sepsis in children the writer advocates the extraction of all deciduous teeth in which the decay is sufficiently advanced to infect the pulp. He generally extracts their antagonists also. He fills teeth only when he is sure that the pulp is not affected. This condemns at once the majority of decayed deciduous teeth, because the pulps of these are relatively larger than the permanent teeth, so that a comparatively small cavity is sufficient to infect the pulp. He treats the permanent molar teeth in the same way as the deciduous teeth if the roots are incomplete at the time of the pulp infection. He knows of no way of dealing with infected pulp in children which he regards as sound. He deprecates the practice of sterilizing and capping the pulp. The arguments for and against the extraction of permanent molars are given. Experience shows that the child regains its normal weight and health after extraction of all septic molars.

4. Acute Intestinal Obstruction Due to Pregnancy in a Bicornate Uterus. C. E. S. Jackson.

2. Tumors Complicating Pregnancy, Labor, and the Puerperium—Lecture I.—Herbert R. Spencer presented notes of thirty-seven cases, illustrating the following points: In a large number of cases of small tumors patients pass through pregnancy and labor without difficulty. Even in the case of large tumors—some as large as an adult's head—no difficulty may arise, illustrated by eight cases. The danger of pedunculated reniform tumors becoming rotated and causing inflammation is illustrated by one case. Retroversion and retroflexion of the pregnant uterus produced fibroids, one of acute anteflexion, and two of inversion of the uterus. In seven cases submucous tumors were removed after childbirth or miscarriage by enucleation through the os uteri. In these cases, although sepsis occurred, hysterectomy was not necessary. Three fatal cases were described, one from nipping of the ileum between two pedunculated subperitoneal fibroids; the second from twisted infected subperitoneal reniform tumor; the third was infected with *Bacillus welchii*, and died of acute sepsis after cesarean section. The after histories were given in many cases, extending in some instances for periods as long as twenty-five years. With regard to treatment, the great majority of cases require only careful supervision during pregnancy, periodical examination of the urine, and rest, mild aperients, and anodynes if the tumors become painful. Induction of abortion, and premature labor and forcible delivery past obstructing tumors are contraindicated. Forceps may be required for inertia, but should never be used to overcome resistance caused by tumors. Craniotomy and embryotomy are called for only in cases in which the fetus is dead and the mother not infected. Polypi and pedunculated subperitoneal tumors should be removed.

2. Concerning Spinal Cord Tumors and Their Surgical Treatment.—Charles A. Elsberg found that of 67 spinal tumors operated upon by him, 49, or almost three-fourths, were extramedullary, while 18, or one-fourth, were intramedullary. In 42, or 62 per cent., of the cases the new growth occurred inside of the dura mater. Of this series of 67 cases, in 27 the tumor lay somewhere between the fifth cervical and the third dorsal, and in 21 between the ninth dorsal and first lumbar segments; in 11 between the lower end of the spinal cord and the roots of the cauda equina. The extramedullary growths occurred with about equal frequency at the cervicodorsal and dorsilumbar levels, while intramedullary tumors were met with twice as often in the cervicodorsal as in the lower levels of the cord. Tumors are most frequently met with on the posterior aspect of the spinal cord. Of the 31 extramedullary (intradural) tumors in the series above the level of the cauda equina, 24, or 77 per cent., lay either on the posterior surface of the cord or posterolaterally, and 14 of the 18 cases of intramedullary tumor seemed to occupy more especially the posterior parts of the spinal cord. In seven patients with extramedullary tumors (33 per cent.) the growth was found either anterior or anterolateral to the cord. Of the sixty-seven patients in the series the diagnosis of tumor was made or suspected sixty times; in the seven other patients a tumor was considered one of the possibilities. In the majority of instances the tumor was found at or near the suspected level. In 48 of the 67 cases the level diagnosis was correct; in sixteen it was too low; in three it was too high. In all but three of the patients the tumor was found either at the suspected level or no more than three segments higher or lower than had been diagnosticated. In all of these patients the growth was exposed after the removal of several additional vertebral arches. In one patient the level symptoms point to a lesion at the sixth dorsal segment, but the tumor was found at a second operation at the twelfth dorsal segment. In two other patients the diagnosis of a tumor at the level of the twelfth dorsal segment was made. The operation failed to expose the growth. A year or more later, in each patient, there were clear level symptoms in the cervical region, and in both instances the tumor was removed from the lower cervical region at the second operation. Of the sixty-seven patients seven, or 10.4 per cent., died after the operative interference; in the operations for extramedullary tumors there was a mortality of 6 per cent. In some of his earlier cases the writer is convinced, from a study of the fatalities, that operative interference should have been refused. If the cases are properly selected, the fatalities after laminectomy for the removal of spinal cord tumors should be no larger than 6 per cent.

5. A Clinical Pathological Study of an Unusual Syphilitic Manifestation Resembling Juxta-Articular Nodules.—Goodman and Young report in detail a case of multiple and symmetrical gummata of the tendons which clinically closely resembled the tumors of juxta-articular nodules. The microscopic picture was very different, however, and hence the two conditions could not be confused. Unfortunately, they were not able to observe the effect of antisyphilitic treatment, but the suggestive history, positive Wassermann, and histology of one of the lesions, convinced the writers of the correctness of the diagnosis of multiple syphilitic gummata of the tendons.

9. The Preparation of a Stable Vitamine Product and Its Value in Nutrition.—H. E. Dubin and M. J. Lewi, proceeding upon the premises that vitamines, as they occur in natural fresh foodstuffs, are of vital importance to satisfactory maintenance and growth; that malnutrition depends not upon insufficient food but upon improperly prepared foods or upon an improper combination of foods; that the thing to recognize is that absence of vitamines leads to poor nutrition; and that if sufficient vitamines are not obtained in the usual diet then the deficiency must be supplied in some other way, thought it desirable to try to prepare a stable vitamine product that would prove effective therapeutically in increasing body growth whenever the nutritive powers of the individual were below par. They succeeded, after extended investigation, in preparing an active vitamine product which they designate as vitamine preparation "V." This is prepared from corn, autolyzed yeast, and orange-juice, thereby assuring the presence of anti-neuritic, antirachitic, and antiscorbutic vitamines. Analysis of this stable vitamine product shows its chief constituents to be calcium, expressed as calcium oxide, 10 per cent.; phosphorus, 15 per cent.; nitrogen, 3.5 per cent.; fat, 2.5 per cent.; iron, 0.3 per cent.; silicates, 5.6 per cent.; moisture, 10 per cent. The remainder goes to make up the rest of the phytin molecule—the main constituent of the product—which is a double calcium and magnesium compound of inosite phosphoric acid. It was found, in their experiments with pigeons, that one gram of this vitamine product given every other day, in addition to polished rice, was sufficient (*a*) to prevent the onset of polyneuritis, (*b*) to cure polyneuritis, and (*c*) to maintain and increase body weight. Encouraged by these results, they decided to determine the effect of feeding the vitamine preparation to children exhibiting a condition that could be attributed to a lack of vitamines in the diet. The cases available for study included children showing evidences of malnutrition, marasmus, and rickets. Two groups of four and ten children respectively were studied. The babies selected were placed in separate cubicles under the constant supervision of day and night nurses; all food was carefully weighed or measured, so that the exact amount eaten was known; the weights of the babies were recorded every other day; and a nitrogen, phosphorus, and calcium balance was run, in the hope of noting any deviation from the normal as a result of added vitamine ingestion. A third set of five babies, receiving their usual diet only, served as a basis of comparison. At the conclusion of the experiment with the first group, all four children showed definite improvement, as a result of the addition of vitamines to their diet, two of the group showing such marked improvement as to bring them up to normal in all respects. In the second group, likewise, the children who received daily doses of the vitamine product gained in weight much more rapidly than did those to whom vitamines were not given. At the end of the experiment it was found that the general condition of the children who had received the vitamine product was somewhat better than that of the children of the control group.

6. The Protection of Vaccination Wounds.—Douglas H. Stewart, in one of his "The Value of the 'No Good'" series of contributions, gives a simple and practical dressing for vaccination wounds, applicable at any stage of their progress. It is made from two pieces of a wooden tongue depressor, placed side by side, and trimmed a little on their narrower edges, so that when laid upon their broader surfaces a V-shaped opening with its apex at the dividing line may appear between them. These pieces, when placed so that the vaccination wound comes within the V-shaped opening made by trimming the ends, will shelter the wound. A couple of strips of adhesive plaster will hold the apparatus firmly in place. The wooden pieces have a tendency to indent and bury themselves in the skin and thus fix themselves in the position in which they are first applied. When such pieces are properly placed the bandage may be applied in the usual way; they may be changed frequently or seldom, neither contact, adhesion nor friction need be considered. Antiseptics may be used ad libitum, once the virus has been allowed a headway or lead of eight days or more. In erysipaloid conditions lead wash or other washes or polyvalent

bacterins may be used locally as desired. All of this may be carried out without disturbing or moving the little wooden protectors. Thus may the fungoids, or the holes or the craters in the skin be avoided.

Grippe and Puerperality.—Beuttner and Vulliéty continue earlier reports on this subject from the Geneva Obstetrical Clinic. No less than 13 categories of data are given as follows: (1) The gravida recovered, pregnancy taking its normal course with delivery at term, taking the healthy infant home with her (7 cases); (2) The gravida died of influenza without labor supervening (one case only); (3) The gravida aborted and recovered (one case only); (4) The gravida aborted and died of influenza (2 cases); (5) The gravida gave birth prematurely to a living child, the mother recovering (one case); (6) The gravida gave birth prematurely and recovered but the child did not survive (2 cases); (7) The gravida gave birth prematurely and succumbed to influenza, the child surviving (one case); (8) The gravida gave birth prematurely, died of the disease, child also lost (2 cases); (9) The gravida was delivered at term in the midst of the grippe, the infant surviving (10 cases); (10) The gravida was delivered at term in the midst of the grippe, the child being lost (2 cases); (11) The gravida was delivered at term in the midst of the grippe, dying in the puerperium, child surviving (2 cases); (12) The gravida was delivered at term, developing grippe in the puerperium and recovering, child survived (8 cases); (13) Same as preceding with fatal exit of mother, child recovering (one case). An analysis of the material fails to bring out any decisive laws about puerperality and grippe, but the material was small—less than 50 cases.

Dietetic Treatment of Renal Insufficiency.—Motzfelt after a digest of this subject based on the recent literature and personal experience, states that the most striking effect of the salt-free diet was seen in the case of a young man with acute nephritis, who in 22 days lost all his edema and 27 kilos of weight, his chlorine output exceeding the intake by 250 gms. While certain flat failures are cited, there were some remarkable results from low protein diet in chronic nephritis. Thus one woman who was admitted with uremic symptoms recovered to such an extent that she was discharged with relative cure. In another case the male patient was in the last stage of chronic nephritis with beginning uremia. During three months of low protein diet the azotemia was reduced from 2.45 to 0.32 grams of urea per 1000 c.c. of blood. Phthalein output increased from 20 to 60 while the blood pressure came down from 240 to 170. He left the hospital able to resume work. The author finds that in certain cases low protein has a remarkable influence over nitrogen retention, the headache, nausea, vomiting, and asthenia disappearing. The phthalein test is the measure of renal improvement. Milk diet is not suited for carrying out either salt-free or low protein diet but each individual must be studied on the basis of his own responses to diet.

Cesarean Section, 1906–1918.—Brandt and Smith during a period of 13 years and 6 months have performed 62 classical and 40 vaginal cesarean sections in the Gynecological Clinic at Christiania. The classical sections were performed for the following indications: narrow pelvis, 27; eclampsia, 17; premature detachment of normally seated placenta, 5; placenta previa, 5, and the balance scattering. Of the 61 cases tabulated 11 ended fatally for the mother, the operation, however, not contributing to the deaths in at least 3, so that the net mortality was 8, chiefly from peritonitis. In detail the mortality was peritonitis 5, septicopyemia 1, pneumonia 1 and secondary hemorrhage 1. Deaths from the original disease were 2 from eclampsia and 1 from uremia. Of the 40 women submitted to vaginal cesarean section 9 died. In 35 the indication was eclampsia and the other 5 sections were placental cases, with 3 premature separations and 2 previas.

Dextrocardia and Dextroversion.—Vaquez and Donzelot state that our knowledge of these conditions is still incomplete. By "dextroversion" they refer to acquired dextrocardia. The incompleteness of our information is bound up partly with the fact that the *x*-ray and electrocardiagraph have only been applied to the study of these conditions in comparatively recent days. Two cases are first outlined in which the patients consulted for cardiac disorders and the beat was found on the right side. In the first there was an extreme thoracic deformity and asymmetry, the want of development of the left chest being responsible for the displacement of the organ to the right. History negative as to pleural or pneumonic affections. Despite palpitations the heart was functionally normal and the electrocardiograms were normal. The radiograms showed that the apex was well to the right. The second case agreed closely with the first, the pulse being somewhat faster than normal—80. No deformity of the thorax is mentioned in this case, and the patient was unaware of his abnormity. A history of pleurisy or pneumonia was not obtained. The condition in both cases was, strictly speaking, inversion of the major axis of the heart from left to right. Our knowledge of these affections is as follows: there is a dextrocardia associated with transposition of viscera and there is an uncomplicated congenital form in which other viscera have the normal position. Closely resembling the latter from the clinical and even genetic side is the acquired dextroversion, the causes of which show much variation. Between the congenital and acquired form of uncomplicated right heart it is by no means always easy to differentiate. Reference works which make of acquired dextroversion a mere consequence of empyema, etc., do not begin to visualize the true state of affairs, for in the author's second case, as in many others, absolutely no idea of the genesis of the case is possible. In theory there may be cases in which the cavities of the heart are also inverted, but the authors know of none.

Radium in Cancer of the Cervix.—Recasens believes that radium is the indication of choice, some of the results obtained being superior to those by any other method. The type of cancer which yields best to radium is the one with the greatest energy of growth, the dosage and filtrage varying with the variety of cancer. In the papillary forms filtrage may be reduced to 1 mm. and even less if the fungosities are completely enveloped in tubes. In ulcerous forms the filtrage should be stronger and dosage higher. In superficial forms the technic should be similar to that for cancer of the integument, using plates rather than tubes. Infiltrated and nodular forms require strong filtrage and high dosage. Marked leucopenia (hypoleucemia) is a contraindication to the use of radium, as is also the stage of cachexia when advanced. Medium doses of eight or ten days intervals are preferred, other things being equal. By radium therapy the author always means the association of the *x*-rays with radium.

Action of X-Rays on Microbian Flora.—Lequex and Chomé sum up their account of this subject as follows: the action of radium salts on cultures varies with the salt and the culture. The organisms most readily influenced by the salts are the gonococcus and streptococcus, while the salts are inert on the coli group, typhoid and paratyphoid B bacilli. The insoluble salts exert no action unless in immediate contact with the culture. The *alpha* and *beta* rays both appear to possess bactericidal properties at a short distance, while the *gamma* rays appear to be devoid of such properties. Further experience with salts might show that certain compounds exert a specific action on certain germs. In positive cases the radium seems to arrest the growth of culture and suppress pigment-formation and agglutination; but a true bactericidal action, save in the case of the gonococcus and perhaps also the streptococcus, has not yet been seen.

Book Reviews.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. A New and Complete Dictionary of the Terms Used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Nursing, Veterinary Science, Biology, Medical Biography, etc., with the Pronunciation, Derivatives, and Definitions, Including much Collateral Information of an Encyclopedic Character. By W. A. NEWMAN DORLAND, A.M., M.D., F.A.C.S., Member of the Committee on Nomenclature and Classification of Diseases of the American Medical Association; Editor of the American Pocket Medical Dictionary. Together with New and Elaborate Tables of Arteries, Muscles, Nerves, Veins, etc.; of Bacilli, Bacteria, Diplococci, Micrococci, Streptococci, Ptomaines and Leukomaines, Weights and Measures, Eponymic Tables of Diseases, Operations, Signs and Symptoms, Stains, Tests, Methods of Treatment, etc. Tenth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1920.

THIS is a reprint of the tenth edition of this well known dictionary, issued in the fall of 1919, containing, the preface tells us, definitions of several hundred new terms, while many definitions and description of terms in previous editions have been considerably amplified. The general features of the recent editions have been preserved in this—the good as well as the bad ones, among the latter being the wretched pronunciation of the French words, the barbarous use of *k* instead of *c* in leukocyte and similar words—a fault copied from Gould's dictionary, and the cutting off of the final *e* from the names of alkaloids, in contravention to the authority of the U. S. Pharmacopœia and opposed to the usage of the best writers on chemistry. Some of the good features are the clearness of the printing, the handy size of the volume, many extensive tables, and a table of the Greek alphabet by means of which one without a knowledge of Greek may be enabled to work out the etymology of the different words.

THE STUDENT'S TEXTBOOK OF SURGERY. By H. NORMAN BARNETT, F.R.C.S. Major, and Officer Commanding 32d South-Western Mounted Brigade Field Ambulance; Surgeon, Bath Ear, Nose and Throat Hospital; Surgeon for Ear, Nose and Throat, Bath War Hospital; Consulting Surgeon for Diseases of the Ear, Nose and Throat, Officers' Convalescent Home, Bath: and Bath Educational Authority; Lately Surgical Registrar and Surgical Tutor, Royal Victoria Hospital, Belfast; Surgeon, Cripples' Institutes for Ireland; Surgical Assistant, Belfast Hospital for Sick Children, and Ulster Hospital for Diseases of the Eye, Ear, Nose and Throat. Author of "Accidental Injuries to Workmen with Reference to Workmen's Compensation Act," Etc. With 79 plates and 143 illustrations. St. Louis: C. V. Mosby Company, 1919.

ACCORDING to the preface, the requirements of the student were chiefly thought of when writing this book, but "the oft-quoted busy general practitioner will find in it all that he is likely to require to help him in the surgical part of his practice." If this statement were entirely borne out by the facts the book would be something of a paragon; but, unfortunately, it falls considerably short of the mark. The book has many good points but certainly the "busy general practitioner" will find it but a slender reed to lean upon in many of the surgical problems that crop up. Barnett has written the major portion of the book but there are also chapters contributed by William Calwell, M.A., M.D.; R. C. Elmslie, M.S., F.R.C.S.; Victor G. L. Fielden, M.D., M.B., B.Ch.; Alexander Fleming, M.B., B.S., F.R.C.S.; R. J. Johnston, B.A., M.B., B.Ch., F.R.C.S.; E. M. Pilcher, D.S.O., B.A., M.B., F.R.C.S.; A. Howard Pirie, M.D., B.Sc.; The Late Cecil E. Shaw, M.A., M.Ch., M.D.; Revised by Marmaduke S. Mayou, F.R.C.S.; and P. Watson-Williams, M.D.; Llewellyn Jones Llewellyn, M.B., M.R.C.S.; W. James Wilson, M.D., B.Ch., D.Ph.; and J. H. Whitaker, M.D., B.Ch., D.Ph.

The arrangement of topics is peculiar to say the least. For instance, it seems strange to plunge the student at once into a 30-page discussion of the uses and technique of application of the *x*-ray in surgery (pp. 32-62) when, presumably, he knows practically nothing about fractures and dislocations, tumors, or other surgical conditions, discussed later in the book, in which the *x*-ray is used as a diagnostic or therapeutic agent. Erroneous or misleading statements occur not infrequently in many parts of the book. For example, Hodgkin's disease is said to be "an uncommon condition met with in youth." From this the student would naturally get the very erroneous impression that the disease does not occur in middle and later life. The general discussion of tumors is covered (?) in the space of twenty pages; though it is only fair to state that tumors are again considered by regions and organs. Considering the fact that this work appeared five years after England entered the war, the section on gunshot wounds is astonishingly poor. For the good of the patient it is to be hoped that the student will supplement his knowledge of acute osteomyelitis elsewhere before he meets with a case in private practice. Evidently the author has not kept fully abreast of the development of American surgery; for while, as a rule, the book may correctly reflect current British methods, the treatment recommended often does not conform to American standards. Among the conditions in which the treatment suggested is antiquated are: stenosis of the pylorus in infancy, where we find "gastro-enterostomy for preference," an operation with high mortality and rarely done now, being superseded by the Rammstedt operation which is not mentioned in this work; burns, no mention whatever of the newer methods; gallbladder disease, cholecystostomy recommended as routine, when cholecystectomy is now generally considered preferable; for hydatid cyst of the liver, aspiration and injection or sewing the cyst to the parietes, incising and packing are recommended as the best treatment, when enucleation is by far the method of choice. On the other hand, certain sections of the work are excellent, as, for example, that on deformities by Elmslie: while the symptomatology and diagnosis of surgical diseases are generally covered concisely and well. In our opinion if one already has a fairly good knowledge of surgery, so that he can pick the good and disregard the bad, he will find much of interest and profit in this work; but we can hardly recommend it to the student, who is not yet able to discriminate.

EXAMENS DE LABORATOIRE DU MÉDECIN PRATICIEN. Par le Dr. GUY LAROCHE. Préface du Pr. CHAUFFARD. Avec 111 Figures dans le Texte et hors Texte. Paris: Masson et Cie., 1919.

AS Prof. Chauffard remarks in his preface to this remarkably practical handbook, there is nothing more difficult than to write a laboratory manual in simple and precise terms, elementary enough to be of service to the general medical public yet at the same time sufficiently comprehensive to embrace everything of practical utility. The author of such a work must be at one and the same time a practising physician and a skilled laboratory worker, and such evidently is the writer of this book. It is of course impossible to give within the covers of any one volume a full description of the technique of every laboratory operation, whether of bacteriological research, of analysis of the various fluids of the body, or of the constantly increasing number of seric reactions, and consequently the author of a laboratory manual of this sort must be gifted with discriminating judgment to enable him to select the simplest as well as the most reliable tests. His office is that of guide and to be congratulated are those whom he leads not astray.

The first chapter of this work treats of the laboratory and its essential furniture and apparatus, and then follow chapters on the use of the microscope, sterilization, culture media, the starting of cultures, stains and staining, smears from the throat and mouth; examinations of serous fluids and serous effusions, of the cerebrospinal fluid, of sputum; blood counts, search for pathogenic agents in the blood; serodiagnosis and complement fixation reactions; examination of the urine, of the gastric contents, of the stool; diseases of the skin; conjunctivitis, otitis, rhinitis, pus studies; determination of renal, hepatic, and pancreatic insufficiency; the ultramicroscope; germ carriers.

The book is of handy size, of clear print, and the illustrations, many of them on insert plates, are well executed and add greatly to the practical worth of the book. The physician with a working knowledge of French can use this manual with much satisfaction.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 4, 1919.

THE FIRST VICE-PRESIDENT, DR. REGINALD H. SAYRE, IN THE CHAIR.

Election of Officers.—The following officers were elected: *Vice-President*, to serve three years, Dr. Rufus I. Cole; *Trustee to serve five years*, Dr. W. Gilman Thompson; *Member of Committee on Admission*, to serve five years, Dr. Sidney Rogers Burnap; *Member of Committee on Library*, to serve five years, Dr. Carl Vogel.

The Etiology of Thromboangiitis Obliterans.—Dr. WILLY MEYER read this paper. (See page 425.)

The Blood Chemistry of Thromboangiitis Obliterans.—Dr. ADOLPH BERNHARD presented this phase of the subject. (See page 430.)

The Pathology of Thromboangiitis Obliterans.—Dr. LEO BUERGER discussed this subject, illustrating his talk with lantern slides. (See page 431.)

Dr. CHARLES GOODMAN said these papers had interested him very much. His experience with thromboangiitis obliterans covered a period of 25 years. During this time, we have studied this disease from all viewpoints. He was not, however, wholly in accord with the views as stated this evening. In 1912 he visited Kuettner's clinic in Breslau. While there, two of the assistants informed him of the frequency of their observation of gangrene, occurring among the soldiers during the Bulgarian campaign. It was his theory in 1912 that there must be a casual relationship between the frequent occurrence of gangrene and the prevalence of typhus. Similar observations had more recently been reported to him by Dr. Zinsser of New York and Dr. Shattuck of Boston, both of whom had been in Serbia during the war. In 1916 he reported three positive serological reactions in a series of 21 cases of thromboangiitis obliterans tested accordng to the methods described by Plotz, Olitsky, and Baehr. The small number of positive reactions in these tests was explained by Dr. Libman in this way: In typhus fever, patients might lose their serological reactions within a period of five months, and one was dealing with the end results of a previous inflammatory disease of the arteries and veins, with the exception of one case. That patient presented acute manifestations of thromboangiitis, and that patient's blood gave the best serological reaction. Emil Wiener, from his post mortems on typhus subjects, stated that the most characteristic pathological evidence of typhus was the extreme fragility of the vessel walls. This might entail thrombotic formation in the vessels of the *lower extremities* and elsewhere. Fränkel concluded that the areas of necrosis shown in the walls of the arteries after typhus must be considered pathognomonic of the disease. Wolff wrote in 1916 that gangrene of the extremities was among the frequent clinical manifestations of typhus and quoted Brauer, who ascribes the development of gangrene to the specific inflammation of the arterial intima. These assertions were furthermore confirmed by other observers, including Jochman, Fisher, and Estlander. In view of the recent interesting developments of the knowledge of the pathology of typhus, he undertook, in 1917, the study of the pathological lesions of typhus especially as regards its predilection for the vessels of the extremities. Through the courtesy of Dr. Libman of Mt. Sinai and the cooperation of the Hygienic Laboratories at Washington and Dr. Park's laboratories here, several guinea pigs inoculated with blood from typhus were sent to him. These animals were observed for various lengths of time and then killed under anesthesis and the specimens removed for histological study. This work was delayed somewhat because it was found that the anatomy of the blood vessels of the extremities of the guinea pig differed in detail from that of the distribution of the vessels in the human being and as there was no published description of the anatomy of the vascular system of the guinea pig at their command, he had to make a personal observation of the anatomy of the vascular distribution in the extremities of the pig. This he was able to do through the courtesy of Prof. Senior of the New York University Laboratories. His work was then interrupted for two years because of his absence in France. Since his return he had taken up these studies again, and as far as he had gone in the observations of the sections of the blood vessels of the guinea pigs inoculated with blood from typhus patients, he had at least two specimens which showed lesions of definite changes not unlike those found in the vessels of human beings suffering from thromboangiitis obliterans. The histological picture was strongly indicative of the presence of an infectious process in the walls of the blood vessels. Further sections would be examined and as soon as more observations had been concluded the findings would be reported.

Dr. GEDIDE A. FRIEDMAN said that from the observations that he had made in presenile gangrene, he would have to disagree with Dr. Meyer that the disease named by Dr. Buerger thromboangiitis was limited to the Jewish race. Dr. Friedman said he had seen the disease in Esthonians and Russians as well as in Hebrews. He had observed thromboangiitis in this country almost exclusively among the latter, because few Esthonians or Russians had immigrated to the United States. No matter what deduction one might make from end pathology in regard to the etiology of the disease, the most prominent factor must be nicotine, as the disease rarely occurred among women, for the reason that the majority of women did not smoke and the few that did, did not smoke to the same excess as men. Experimentally, it was of interest that if one injected nicotine intravenously into a rabbit, vasoconstriction of the rabbit's ear, foot, or mesentery would be observed, while injection into a dog, caused vasodilatation of the lip to be noticed. He mentioned this in regard to Dr. Buerger's question why nicotine should affect only certain perpheral vessels. It might affect the latter for the same unknown reason that wood alcohol mainly affects the optic nerve. Many, as Dr. Meyer, had thought that thromboangiitis was possibly due to excessive smoking. He agreed with Dr. Meyer, but really believed that so far he is not on the right track. He emphasized that thromboangiitis was due to smoking tobacco of a low grade. In Russia, "machorka," the lowest grade of tobacco, was frequently used by the poor and it was among this class that thromboangiitis occurred. If the disease would have been due to cigarettes of a better quality, the disease would probably be a common one and would not spare the rich. In regard to typhus fever as an etiological factor in thromboangiitis, Dr. Friedman recalled from his experience that presenile gangrene occurred in some cases of typhus, but he absolutely disagreed with Dr. Goodman that typhus fever was the chief etiological factor. If thromboangiitis were due to typhus we should find the disease as frequently in women from Russia as in men, because typhus fever afflicted both. Thromboangiitis was not liable to occur after typhus than after typhoid or any other infectious disease. It might be that in smokers of low grade tobacco, infection is an additional cause, lowering the resistance of the vessels; but the chief agent must be tobacco of a low grade. It would be worth while repeatedly to inject nicotine or extracts of low grade tobacco into animals in order to find out if it was possible to obtain experimentally the picture of a condition of which the pathology was so well worked out by Dr. Buerger.

Dr. H. P. DE FOREST said that he had lived and practised in Brooklyn from 1890 to 1902, where he was in charge of the pathological laboratory of the Methodist Episcopal Hospital. One of the first patients he saw in the beginning of his practice was a Russian Jew, a dealer in art illustrations, lithographs, and other reproductions in colors, who was a smoker and drank considerable beer. He complained of trouble with a hand and a foot. Little by little his condition became more and more painful and more and more severe. He was seen in consultation by a half dozen of physicians, friends of the speaker, without any of them arriving at a diagnosis. Finally he was seen by Dr. Browning who suggested that the man had Raynaud's disease. The circulatory disease progressed, gangrene began, and one foot was amputated. The man was put on a

suitable diet, the alcohol and tobacco stopped and arsenic and iron administered. He had written up a report of the case and had the galley proof of the article when the man died, and at autopsy in dissecting the vessels he found the same picture that Dr. Buerger has presented. His pictures might have been taken from their sections. The picture did not tally with that of Raynaud's disease described in the article, so the galley was never sent back and they came to the conclusion that the man was suffering from the disease described this evening. Following this he had another case and one quite recently which had given him a better knowledge of the condition, and a different conception of the etiology than that expressed this evening. The three men he saw suffering from this condition were all engaged in occupations which brought them into contact with finely powdered metal, particularly bronze, and, while alcohol and tobacco might be a factor in lowering the vitality, it seemed possible that there might be a definite specific neuritis due to the copper, just as we had a specific neuritis due to lead and arsenic. It seemed possible that copper might be operative in producing this disease because not only did the blood vessels show thrombotic changes but sections of the spinal cord and sciatic nerve showed degenerated bands of fibrous tissue. While still open to conviction he felt that copper might be the specific cause of this condition.

Dr. Otto Hensel stated that he had performed certain experiments, injecting metals into dogs, and they never got the lesions of thromboangiitis obliterans. The changes were very much like those produced by adrenalin and were chiefly in the media of the blood vessels.

Dr. Fenton B. Turck stated that he was very much impressed with the observations made in the course of a study of some cases of thromboangiitis obliterans at the Hospital for Deformities and Joint Diseases with the idea in mind that this disease was associated with the products of autolyzed tissue. There was reason to believe that these individuals were incapable of forming antibodies against their own autolyzed tissue and they showed a lack of immunity to their own autolyzed tissue. This idea seemed to be borne out by the fact that in the normal individual the injection of a 0.5 c.c. of chloroform caused no great reaction, but if one injected 0.05 c.c. of chloroform into one of these patients a considerable reaction ensued. We were all producing autolyzed tissue poison and the antibodies against it, and in the normal individual there was an equilibrium between the products of the autolyzed tissue and the antibodies, but in these people with thromboangiitis obliterans there was evidence of a specific lack of immunity to their own autolyzed tissue. One of the results of this devitalization of the tissues was a backing up of the blood in the small arteries and venules which resulted in coagulation of the blood in these small vessels as a consequence of adsorption phenomena. Working on this theory they had injected some of these patients suffering with thromboangiitis obliterans with the antitoxins of autolyzed tissue, and this treatment seemed to produce symptomatic results at once, hence he believed that it was in this direction that they should seek the solution of the problem. Whether any race showed a lack of antibodies as a racial characteristic was a question to be investigated, but it seemed very certain that the individuals suffering from this disease had this deficiency.

Dr. Henry W. Frauenthal stated that he had seen nearly 900 cases of thromboangiitis; 20 per cent. of these cases claimed they never smoked and some had taken up smoking for its anodyne effects so as to relieve their pain; about 35 per cent. of these cases resulted in amputation of the toes or other portions of the leg. He had seen a number of patients who had the disease between the ages of 17 and 30 and he did not consider that they had smoked long enough to become saturated with nicotine. If, as Dr. Meyer stated, nicotine was the real factor in the disease, it should be very common in natives of this country, many of whom smoked as many as 100 cigarettes daily. Ninety per cent. of the cases he has seen were Russian, Polish, and Austrian Galicians, and it therefore seems that the disease was characteristic of a location. During the recent meeting of the American College of Surgeons, he showed a number of these cases to Sir Robert Jones of Liverpool who said that in his large experience he had never come across any of these cases. Inasmuch as the English were great smokers, he should find some cases among them. It was odd that this disease should never occur in women, although women had obliterating endarteritis from diabetes and other causes. Ninety per cent. of these cases in men came from the restricted district of Galicia. A percentage of these cases occurred in the American born whose parents were born in Galicia. He had seen quite a few cases in native-born Americans, and in one case the parents and grandparents were born in this city and the great-grandparents came from a city along the Rhine. One of the cases referred to by him by the Rockefeller Institute, Mr. H., who was of Scotch descent, was a farmer in Florida. Another interesting case, that of an active practising physician in New York, who had one leg amputated at the Presbyterian Hospital and whose other leg he had succeeded in saving by treatment with white light; the patient was born in Ireland. So we undoubtedly had sporadic cases among all nations.

Dr. Willy Meyer, in closing, emphasized the fact that he had in his paper attempted to discuss only the etiology of thromboangiitis obliterans. He said he had the highest appreciation of Dr. Buerger's work but as he was not a pathologist he would not attempt to go into the details. However, he thought Dr. Buerger's observations referred particularly to the end results, because when a patient developed gangrene he no longer had the earlier stage but the end result of the disease. There were many varieties of gangrene and there was one variety, Raynaud's, which had to be kept in mind. It seemed significant that they should have found at the Lenox Hill Hospital in every instance in which they examined the blood for sugar a hyperglycemia. Further search showed that in quite a number of other troubles there was a hyperglycemia; therefore they set it aside as characteristic of this disease. However, it seemed to point to the fact that they had produced by various causes a disturbance in the glands of internal secretion. Of the patients he had seen every single one smoked for many years. If a patient having typical thromboangiitis told him he had not smoked, he thought either that the patient did not tell the truth or else he had another type of gangrene and not the variety designated as thromboangiitis obliterans. Surely many people smoked an enormous number of cigarettes and smoking was very prevalent in many countries where they did not get thromboangiitis obliterans. In the type of people who got thromboangiitis obliterans there was additional nervous trouble due to hypofunction of the sympathetic nervous system. Personally he had found the disease only among Hebrew immigrants. He thought in one instance that he had found it in an Irish boy, but closer inquiry revealed the fact that the boy's father had come from Russian Poland and had married an Irish woman. Why the Esthonians had the disease he could not explain. Dr. Ochsner reported having found it among the Scandinavians and it is said to have been found among the Japanese, but whether the disease was the same as that which we call thromboangiitis obliterans he did not know. Dr. Goodman's statements were entitled to careful consideration. He had, since reading his remarks on the possible relationship of typhus fever to thromboangiitis obliterans, asked every patient whether he had had typhus fever and in every instance the reply was in the negative, and he had always believed that typhus fever had nothing to do with this type of gangrene. No one had ever been able to explain why men were affected and not women. He had tried to blame it on the genital sphere and had even thought of tying the spermatic cord to see what effect that procedure would have on the disease but had desisted. He believed that every symptom of the disease could be explained by the continuous poisoning of the system with the many poisons contained in tobacco, and so far we did not find inveterate smokers among the female sex. He acknowledged that what he had brought this evening were theories and hypotheses; but if the paper stimulated to further discussion and further investigation he was satisfied.

Dr. Buerger, in closing, said he wished merely to

add a word concerning the influence of tobacco. Erb, many years ago, in writing of the influence of tobacco on vascular diseases, called attention to the lesions of the intima of the popliteal and other arteries of the lower extremity and attributed the alterations to tobacco, and Dr. Buerger said he believed there was a great deal of truth in this theory. If many of these cases of thromboangiitis obliterans were followed it would be found that in the majority of instances the patients did smoke. However, when one encountered patients who deny absolutely that they had used tobacco one could scarcely feel as had been suggested by Dr. Meyer that the patient was not telling the truth. Another point that should be borne in mind was that the disease did occur occasionally in women, and, of course, in such instances the objection might be raised that the disease was not true thromboangiitis obliterans. His idea was that although tobacco might play a rôle in the production of arterial disease (no matter what the variety of the thrombosis), it certainly did not produce the typical picture characteristic of thromboangiitis, and furthermore if tobacco was the cause why should it produce that characteristic picture in some cases and not in others?

SECTION ON MEDICINE.

Stated Meeting, Held October 21, 1919.

DR. EDMUND P. SHELBY IN THE CHAIR.

Manifestations of Influenza During the Earlier Periods of Its Appearance in France.—Dr. HANS ZINSSER made this presentation which he prefaced by stating that there was not much to be said on the subject because the epidemic remained in its early stage for a short time only. When influenza began to enter the army and to attack the civilian population the Pfeiffer bacillus was supposed to be the cause. A number of observers in France expressed themselves as being doubtful as to whether this organism was in reality the cause of the epidemic, and there is still much uncertainty on this point. However, there was now some evidence which gave a better basis for an opinion than we had last winter. There was a confused mass of data which many investigators had attempted to analyze. Dr. Park and his associates had come to the conclusion that the Pfeiffer bacillus was the most likely cause of the disease, though actual proof was still lacking. They had been accustomed to think of influenza as a respiratory disease. As a matter of fact many of the early cases did not have any of the characteristics of a respiratory disease though he believed it was the same disease that they saw later. In the Spring of 1918, the disease appeared in Italy, Southern France, and Spain. Dr. Ward MacNeal, working in the Division of Laboratories under Colonel Siler, had compiled the history of the disease in the American Expeditionary Forces from available records. According to his study the first outbreak among American troops occurred at rest camp No. 4 near Bordeaux, in the latter part of April and early part of May. Another outbreak occurred among the men in a company of marines stationed as headquarter's guard at Chaumont. When this outbreak occurred Dr. MacNeal was sent there with a mobile laboratory and the speaker joined him later and together they made investigations. It was impossible to state accurately the number of cases that occurred because cases were so mild that many did not even report at sick call. There were certainly over 300 cases that could be traced and probably a great many more, because occurring at headquarters there were many casuals, transportation outfits, and scattered units of troops, field clerks, etc. The clinical character of these cases was extremely uniform. Base Hospital No. 15 was situated at this place, the director of the medical service at this time being Doctor Vaughan. The severe cases were hospitalized and laboratory studies made. The onset of the disease was uniformly sudden; a very few cases had a preliminary coryza. There was a remarkable uniformity in the history of the cases, examples of which were as follows: a man would go to bed perfectly well, would wake up during the night with headache, would try to get up, and would find that he was dizzy, nauseated, and sick. There were no focal symptoms and no catarrh. A few men had sore throats and a very few had coughs and slight bronchitis. The time of onset could be definitely ascertained to the hour. The temperature ranged from slightly above 99° F., to 101.5°, 102°, or even to 104° F. in some instances. The general picture was one of very severe systemic fever. There was pain in the head, eyeballs, muscles of the back and legs, and these symptoms were practically uniform. There were no enlarged spleens, no rashes, and in fact absolutely nothing definite. One could usually make the diagnosis from the above mentioned symptoms which were largely subjective. The blood counts were very irregular; some showed a leucocytosis of perhaps 1,250; most of them showed slight leucopenia; there was a relative lymphocytosis in most cases. The possibility of pappataci or sand fly fever and of dengue was considered, and insects were studied without their being able to show any relationship between prevalent insects and the sick. As a matter of fact there were practically no mosquitos or other insects at this time in or around the barracks, flies had not been a serious pest, and living at headquarters the men were not lousy. The striking thing about this epidemic was the mode in which it attacked units. In many cases it hit a unit almost in a day, so that it must have been due to some factor that struck many men at the same time. When such a thing occurred the most natural thing was to look into the food supply. A consignment of bad meat had come to them just at this time and complicated the question, but as the disease appeared at about the same time among French troops where there was no possibility of its being ascribed to the food, this factor as a cause of the epidemic was also ruled out. It soon became evident that they were dealing with a disease that could unquestionably be transmitted directly from person to person. Every member of the attending physicians' office who examined the men with this disease and looked down their throats got it, sooner or later. Both throat cultures and blood cultures taken at that time were entirely negative. Doctor Zinsser quoted from a report written at the time in which they had made the statement that they were not at all certain that they were dealing with "grippe," and thought that it might be a disease due to a filterable virus. While making such investigations as were practicable they definitely made up their minds that experiments on human beings on a large scale were out of place at this time for research purposes, owing to tactical conditions. The speaker was next ordered to the 42d Division, where they were beginning to have the disease, and where, at Baccarat, it was occurring in battalions that were doing trench duty. Large numbers of men came down with the disease, but many did not even report at sick call. Most of the men who did report were set at light duty or quarters, and in a few days returned to their regular duties. Here again the striking feature was the way in which the disease attacked almost entire battalions in a day. In one company sixty men came down with the disease in one day. About this time the symptoms began to include sore throat and mild bronchitis, and there were a few bronchopneumonias. In smears taken from the throats they began to find the influenza bacillus. In many instances also, there was a Gram-negative micrococcus which was extremely minute when brought under partially anaerobic conditions in ascitic fluid. It was impossible to say anything definite about the bacteriology at that time. There was again evidence of person to person transmission in the scattered cases. He felt that the disease as it appeared was unquestionably influenza, since many cases that were much more severe had the same basic character with a superadded respiratory infection which was different in different places, the hemolytic streptococcus and other varieties of streptococci predominating in some places and the pneumococci in others. His impression was that influenza in its pure, uncomplicated form was a very mild disease which was not accompanied by respiratory symptoms and from which the patient recovered in a few days, and had it not been for secondary infections it would have caused neither any serious military problems nor any considerable death rate. In spite of the sudden seizure of many men of a single unit on one and the same day, he believed that food and water were not causative factors of the disease. The only clue to help explain this form of

sudden occurrence within a short period in one and the same group, was the fact that in the 42d Division the outbreak was preceded by marches in the dust. In this connection it is interesting to note that the British had observed that the incidence of dysentery seemed to be increased in relation to dust. Desiccation did not always kill bacteria, as was shown by Stillman's recent experiments in respect to the pneumococci and the same was true of poliomyelitis. On leaving the Baccarat region Doctor Zinsser returned for a brief period to Dijon for report to Colonel Siler, and on arrival found fourteen cases in the very early stages of the same disease in a Motor Transport Unit living in barracks two miles outside of the city. With Doctor MacNeal early throat cultures were taken on special media from fourteen of these cases, and in all of them influenza bacilli were found by the speaker and by Doctor MacNeal, either morphologically or in culture. As to the etiology it seemed that we must take the ground that we had thus far no definite etiological findings. Several British investigators had been inclined to believe a filterable virus was the cause of the disease, but later evidence seemed to discount this. Blake found that by a pure influenza bacillus he was able to transmit influenza to monkeys. Richard Taylor by taking smears from the large bronchi found influenza bacilli more numerous in proportion as they were taken nearer the pulmonary alveoli. A definitely filterable toxin which passed a Berkefeld filter had been found by Mrs. Parker in the laboratory at the College of Physicians and Surgeons, and while it had not the potency of diphtheria and tetanus toxin, 2 c.c. would kill a rabbit. Study on this toxin was still in progress at the above named laboratory by the worker mentioned, and the discovery of a potent poison of this kind would explain the systemic infection and somatic muscle pains even in cases where perhaps there was only a relatively slight infection of the throat. It was the opinion of the speaker that while the etiology of influenza was not definitely determined, the above facts would seem to place the influenza bacillus in the most important place among the suspected organisms. Other organisms, like pneumococci, streptococci, etc., could be definitely regarded as purely secondary infectors to which the disease seemed to predispose to a high degree. The great frequency with which very small Gram-negative micrococci were found in the throats must be borne in mind when bacteriological investigations were made on the throats of early cases. The discovery of the virus must, of course, not be considered impossible, and this subject was being accurately investigated in many laboratories in the United States at the present time. The chief points of the above remarks were the fact that influenza without complications must be thought of as a systemic infection without any respiratory complications, and the entire disease could run its course, if a certain mild one, with nothing more than slight reddening of the pharynx. It was by the study of such early epidemics in their pure state that eventual etiological certainty would be obtained.

Dr. HARLOW BROOKS suggested that the rapid spread of the disease in the camps might have been due to infected mess kits. Certain predisposing factors might also play a part in the dissemination of the disease. It was interesting to note that Zenker's degeneration was observed not only in the recti muscles but also in the psoas muscles in some cases of influenza.

The Argonne Influenza Epidemic.—Dr. HARLOW BROOKS and Dr. CURTENIUS GILLETTE based this report upon cases observed in the field and evacuation hospitals of the first Army, then operating in the forest of the Argonne, during the months of September and October, 1918. There could be no question as to the highly contagious character of the infection in the army area, as evidenced by numerous examples of direct contact transmission among the troops and especially among the overworked officers and enlisted men in charge of the cases. The predisposing factors, however, concerned in the spread of the infection at the front were more obvious than was apparent in the troops and hospitals, or in the camps at home. Reports from civil and military physicians then in charge at home confirmed the opinion that the type of the infection in the United States and on the transports was much more virulent than that seen in the area of the first Army. Exposure was the first and most important of the predisposing factors. The second factor in grade of importance was apparently that of exhaustion. The third factor of great importance in predisposition undoubtedly was to be found in the inadequate and irregular feeding of the troops. A fourth predisposing factor, for cases which occurred on the fighting line, was gassing. Overcrowding in billet, dugout, and bivouac, and direct transference of infection from case to case, was apparently not an important factor at the actual front. In the field hospitals, also, this was believed to have been a relatively unimportant matter, since, except perhaps under conditions of very great military urgency, the field hospitals definitely attempted to isolate these cases from others, and particularly from the wounded or gassed, nor were cases of influenza usually evacuated from the well conducted field hospitals in the same ambulances or trucks as those conveying cases suffering from traumatisms. In certain of the larger evacuation hospitals further back these precautions were not taken, and overcrowding and direct personal transmission of the infection was favored by slack and indifferent methods of triaging and of warding patients. Infection from the improper cleansing of mess kits in overcrowded dugouts at the front was doubtless a real factor in many cases. The transporting of patients with influenza and pneumonia in crowded ambulances and hospital trains together with the wounded and gassed patients, contributed largely to the spread of the infection. Some of these errors were overcome later. The three classical types of the infection were clearly distinguishable—the catarrhal, the gastrointestinal, and the meningeal. By far the greater number of cases belonged to the first class; indeed, all the cases showed to a greater or less degree the symptoms of catarrh of the respiratory tract. The manner of onset was practically identical in all cases. As a rule the immediate onset of the disease was preceded by several days of indisposition, malaise, and depression, generally attributed by the patient to the natural exhaustion consequent upon his military exertions and the conditions of life. The observers believed this to have been usually a receptive condition rather than an incubation period. In some cases, chiefly those in which the disease was contracted by the direct transference of the infection, the onset was sudden and was introduced by a chill or by fever. As a rule there were two or three days, though sometimes but a few hours, of nasal catarrh, of sneezing, of coughing, and of conjunctival injection. Physical and mental depression of a very marked degree was almost invariably present. In the catarrhal or respiratory type of the disease, further progress was practically through an extension or accentuation of these symptoms. The temperature, which was often introduced by a chill, would rise rapidly to the level of 102° or even 106° F. by rectum. The pulse rate was not proportionately quickened but it was usually accelerated to a considerable degree. The respiratory rate was increased, even in patients who as yet showed no demonstrable pulmonary lesion. It was notable in this epidemic that symptoms of pneumonia usually preceded considerably the appearance of signs justifying the diagnosis. The leucocyte count was not usually increased, and a leucopenia might be present while the differential count showed a relative increase of the mononuclear elements, or no change whatever. The urine was entirely negative, except in patients with very high fever, when a febrile albuminuria appeared; and though heavy sweats were frequently seen together with marked thirst, the amount of urine was frequently notably diminished and the acidity so increased that patients themselves remarked its acid and irritating character. Physical examination was largely negative except as to the respiratory tract. The mucosæ of the pharynx, nose, and eyes were hyperemic, and the soft palate was sometimes suffused to the point of induration, and was of a dusky red color. There was a marked increase of nasal discharge of a clear watery character, and the lacrymal secretion was much increased. Many autopsy records showed involvement of the accessory sinuses. In the lungs, particularly over the bases, fine crackling râles were found. Pain was complained of under deep respiration, and râles were usually most abundant over the bases posteriorly. The

percussion note in most instances was even thus early hyperresonant especially latterally and over the bases. The patient's complaints were, first of depression, exhaustion, pains all over the body but particularly in the loins and in all the muscles of the calves. Irritating cough and "stuffed up nose" were also complained of. Appetite was slight, the bowels usually loose. The "sick all over" complaint was frequently made. Most patients who, at this period of the infection, were provided with warmth, rest, and a light, hot diet, recovered within a very short time. The average length of time in the hospital for these patients was three and a half to four days, though they were much depressed and weak. Under favorable conditions one might confidently expect as high as seventy per cent. of the men to be returned to duty within a week. Complications, particularly bronchitis and pneumonia, were apt to arise at any time in the course of the disease, but especially in those prolonged though mild manifestations which would hang on for weeks in patients who were unable to secure the necessary attention in the way of rest, warmth, dryness, and proper feeding. Diffuse bronchitis was probably present in all patients. In those cases in which the disease went on to the development of clinical pneumonia, as a rule the process was distinctly a progressive one and could be traced either with the fluoroscope or by the ordinary methods of physical examination. Cutaneous emphysema was not an uncommon occurrence. The mortality rate in cases of pneumonia was high when the process became compact or widespread. A few of them terminated with a typical crisis, but most of those of favorable outcome convalesced by a slow return of the temperature by a lysis, usually of long duration. None of the patients except those with but slight pulmonary involvement recovered or convalesced rapidly. Pleurisy was practically constant in those patients in whom the pneumonia was compact and when it reached to the surface. The gastrointestinal cases were second in occurrence to those of the catarrhal type, the chief difference which marked these from the catarrhal cases being the predominant symptom of diarrhea. The stools were very frequent, were watery, and contained a good deal of mucus, but seldom blood. The meningeal type of influenza was not frequent. The dominant symptoms were those of a very severe prostration, excruciating and very persistent headache, slight stiffness of the neck muscles, occasionally some accentuation or irregularity of the knee jerks and an occasional and transient pseudo-Babinski reaction. Occasionally a slight and inconstant Kernig reflex was found. Lumbar tap showed no apparent microscopic change in the cerebrospinal fluid, which was sterile, but in the patients showing symptoms of cerebral irritation pneumonia was likely to develop and with it an early delirium of particularly active character. In several of these patients true streptococcus or pneumococcus meningitis was found, but the so-called influenza bacillus was never isolated from the meningeal exudate. Other complications than pulmonary and intestinal were very rare in this epidemic. In the way of management it was pointed out that the two most essential factors in the treatment of all forms of the epidemic were rest and warmth. These alone, in most early cases, predisposed to recovery.

Dr. Warfield T. Longcope said that the subject had been so well discussed by both men that there remained little to add. However, there were two matters of which it might be worth while to speak, though they might be considered as sequelæ rather than as a part of the disease. He had been interested in November and December of 1918 in the cases of bronchitis, as well as in other varieties of respiratory infections, including occasional lobar pneumonia from which type pneumococci were recovered, that prevailed in France after the epidemic of influenza. The picture, however, was quite different from the complicating pneumonias of influenza. It seemed very probable that we were dealing with what might be called a hang-over infection from the epidemic. It would be remembered that the early outbreaks were spoken of as a three-day fever and the cases were rarely complicated by respiratory infection. Later the complicating respiratory infections, caused by the streptococci and other organisms which acted as secondary invaders, rendered the originally mild influenza a very fatal disease. In November of 1918 these secondary infections reached their height and caused a terrific mortality. Later it seemed as though the influenza had subsided but the secondary invaders, their virulence and invasive power being much enhanced, spread from one to another normal individual as they would not have done under ordinary circumstances, and gave rise to the multiplicity of respiratory infections following the actual epidemic. The other piont was in regard to the actual complicating pneumonias in influenza patients. Inasmuch as in many of the base hospitals there were cases in which the signs of irregular consolidation persisted sometimes for weeks, with cough and actual hemorrhages together with fever, the condition was often considered to be tuberculosis. However, no tubercle bacilli were found and the patients eventually recovered. The *x*-ray in these cases showed some dilatation of the bronchial tree and it was probable that the subacute infection of the lung had produced bronchiectasis. In view of these facts it might be supposed that during the winter we should see many cases of bronchiectasis. As a matter of fact, the speaker had seen quite a number of cases of bronchiectasis from which the influenza bacilli were cultivated in practically pure culture.

Dr. Haven Emerson quoted statistics of the incidence of influenza in December, 1917, and January, 1918, and for December, 1918, and January, 1919, which showed that there was practically no difference in the incidence of the disease in these two periods, and stated that it seemed quite possible that the incidence of influenza was equally as serious during the winter preceding as when it was recognized among the two million men in our army. Other statistics of interest were that among 220,000 cases, the death rate from influenza not complicated by pneumonia was 1.2 per cent. The death rate among cases in which pneumonia was recognized was 4.37 per cent. It was of interest also as a matter of comparison that the death rate from influenza and pneumonia, as a whole, in our army was 6.196; in the British Army among 104,000 men the death rate was 6.75 and in the French Army, among 131,000 men, it was 7.21 per cent. As to the comparative value of these statistics, one could not be quite sure as it was doubtful if we could claim equal or comparative methods of reporting the incidence of disease. In the American Army the epidemic reached its height in the week of Sept. 22 to Oct. 1; in the French Army, the disease reached its height during the week from Oct. 12 to Oct. 20, and in the British Army during the week of Oct. 27 to Nov. 2. It therefore swept from the American to the French, to the British armies.

Dr. George Dow Scott said that while he did not see as many cases of influenza in adults as he saw in infants and children, he had nevertheless been impressed by the fact that the disease presented many curious phases. He related that Professor Dunbar, an American, who was head of the Hygiene Institute in Hamburg was sent by the German Government to Manchuria to investigate the plague that was raging there in 1915. Later Professor Dunbar prophesied that within three years the Manchurian plague would have spread all over the world, and within a period of three years we had this tremendous epidemic. It was not a true epidemic of influenza, Dr. Scott believed, but the Manchuria plague, a typical influenza, if one wished to call it so, modified according to conditions in different localities. He mentioned the Manchurian plague because it had always been a question in his mind whether this epidemic was one of true influenza.

Dr. Maurice Fishberg stated that the points brought out in reference to the incidence and etiology of influenza in France could be correlated with facts observed among the civil population in New York City during the fall and winter, 1918-1919. Here it was observed that mainly the previously strong and healthy were most likely to succumb to influenza and its complications. Those affected with chronic diseases, especially of the respiratory tract, as chronic bronchitis, bronchiectasis, asthma, pulmonary emphysema, tuberculosis, and the like, stood influenza well; nearly all recovered. The young, the robust, and the strong, were more likely to develop bronchopneumonia and to succumb to it than the weaklings, the chronically sick, and the decrepit. Observations made at Framingham,

where the Community Health Service had had detailed statistics of the general health of the population, were to the same effect: Those suffering from pulmonary tuberculosis, active or quiescent, suffered less from influenza and its complication than the previously healthy. Dr. Fishberg thought that gassing had very little to do with the course of, and mortality from, influenza among the soldiers of the A. E. F. in France. As to the observation made by Dr. Brooks that some patients developed cutaneous emphysema, Dr. Fishberg stated that similar cases were observed in this city. In most cases the emphysema was but a complication of pneumothorax which preceded it and was probably due to rupture of some air cells caused by cough, or by loss of continuity in the visceral pleura owing to the pathological process in the lung. Dr. Fishberg had not been convinced that rigid rest immediately instituted was a sure preventive of complicating bronchopneumonia. He had had patients who refused to go to bed, but kept on working despite symptoms and signs of influenza, yet they did not develop bronchopneumonia. It appeared that those destined to develop pneumonia did so irrespective of the treatment instituted, and signs of lung complications could be elicited within twenty-four hours after the onset of the disease. These patients were unable to be active or to work even if they wanted to do so; the acute fever and debility were pronounced. It was curious that our preconceived notions about the sequelæ of influenza had been somewhat shattered since the recent epidemic. Many patients had pulmonary hemorrhages during the course of influenza, and some had hemoptysis after the acute symptoms had subsided, but he had not seen a single case of pulmonary tuberculosis which developed after influenza. Most of the pulmonary lesions after influenza consisted in bronchitis, bronchiectasis, or pleurisy. In only two cases admitted under his care to the Montefiore Hospital did it appear as if the tuberculous lung lesion followed an attack of influenza, but careful study revealed that in one case the tuberculous nature of the lesion was rather doubtful, while in the other the history showed clearly that the patient had had tuberculosis before the symptoms of epidemic influenza made their appearance.

Dr. Gedide A. Friedman spoke more particularly of the gastrointestinal type of influenza. He said there were cases in which it was doubtful if one could consider them as a purely gastrointestinal type, since slight nervous and respiratory disturbances were also present, but he felt sure there were really cases of gastrointestinal variety. He would not emphasize the existence of such a type had he not observed these cases in families in which typical cases of influenza existed. One member of a family would have the respiratory type of the disease and another member of the same family would come down with diarrhea, colic, or vomiting. There was no doubt in his mind but that there was a gastrointestinal type of influenza and if there was such a type it made very doubtful the theory that the primary seat of the disease was the respiratory tract. He had had cases in which the only symptoms were fever without cough, throughout the febrile period. In other words, one could not conceal the fact that the disease, influenza, was a general infection. Dr. Zinsser had referred to the infection of masses of people simultaneously. That was not alone characteristic of influenza, but was also true of typhus fever. In a week or sometimes within a few days many would be affected with typhus fever in prisons. A question that came to his mind was whether any experimental work had been done in reference to the transmission of influenza by insects, just as in typhus or Texas fever or other infectious diseases. Thus far there was nothing on this phase of the subject in the literature.

Dr. Zinsser, in closing, said that he had not intended to imply that a sudden onset occurred only in influenza because, as they all knew, this occurred in a number of other conditions, especially such as those conveyed by ingestion with infected food. The disease could not be attributed to lice because the marines were living under particularly good sanitary conditions, they were not troubled with vermin, and were in a condition of exceptional fitness. There were no mosquitos and no sand flies in the region, and in fact no insect to which the infection could be attributed. In regard to the question asked about influenza prophylaxis, nothing specifically could be said. The general prophylaxis was that used for respiratory diseases in general, the prevention of the transmission of sputum as in spitting, coughing, etc., by wearing of masks. But since the hour was late it might be best not to enter upon the subject of our specific influenza prophylaxis, and it was premature to say anything more about vaccination.

Dr. Brooks expressed the opinion that Dr. Fishberg's comparison was scarcely a fair one, when he compared groups of men of the same age and same condition under military discipline with the civil population as a whole which was made up of people of all ages under very variable conditions. As to the frequency of bronchiectasis, they were finding a large number of cases at the present time. He had seen more cases of bronchiectasis this autumn than during ten years before.

Typhoid and Paratyphoid Incidence and Deaths in the A. E. F.—Dr. Haven Emerson read this paper in which he stated that from July 1, 1917, to May 31, 1919, there were 1,242 cases of typhoid fever in the A. E. F. with 155 deaths, or a case mortality of 13.2. During this same period there were 169 cases of paratyphoid fever with four deaths, one from paratyphoid A and three from paratyphoid B. Including the cases of both typhoid and paratyphoid the case mortality was 11.25. For the French Army during the same period the combined death rate from typhoid and paratyphoid fevers was 9.76. In addition to typhoid and paratyphoid fever there was a considerable number of benign enteritides among the troops of the A. E. F. Conditions were such that a thorough study of these cases in respect to the organisms concerned and a diagnosis on the basis of the laboratory findings as well as the clinical symptoms was impractical. At one convalescent camp, during December, 1918, and January, 1919, a considerable number of patients came who had been treated for influenza eight weeks earlier. The attitude of the medical officers throughout the A. E. F. was such that they did not like to report typhoid or paratyphoid fever. The intestinal type of influenza served to obscure the diagnosis of subacute enteritides, dysenteries, etc. The medical officers seemed to have an idea that, owing to protective inoculation, they would not find typhoid or paratyphoid fever. They were seemingly deaf and blind to the evidences of these diseases. Dr. Emerson related the history of three very definite epidemics of typhoid fever occurring in the A. E. F. one occurring in the Argonne region and including the personnel of a hospital there, a second in a traction company in Marseilles. In both instances the application of well known sanitary procedures served to check the epidemic. In certain regions of France typhoid fever was endemic and it was probably only because of prophylactic inoculation that severe epidemics were prevented, as it might be recalled that there was an epidemic of typhoid fever in the French Army early in the war before it was possible to inoculate the soldiers against typhoid and paratyphoid. The third epidemic of typhoid fever which the speaker described was that occurring in the Camp Cody replacement company of 250 men of whom 99 came down with the disease. These men had all been vaccinated in different camps in the United States and by different medical officers. It seemed that this outbreak could be explained only by what might be called a massive hand to mouth infection. It seemed that the source of the infection was a water barrel attached to a kitchen car at Camp Cody. The Marseilles epidemic was due to failure to recognize large spleens, abundant roseola, and, at autopsy, Peyer's patches and even intestinal perforations. Failure to recognize early cases and exposure to massive doses of infection appeared to be the reason the protective power of prophylactic vaccination was overcome. There was no reason to believe that vaccination did not afford the greatest protection against typhoid and paratyphoid fevers. It was of the greatest value in our forces who were exposed to infection at countless points. In closing, Dr. Emerson urged the need of recording the weekly change in population in connection with the rates of incidence and mortality of disease.

Dr. Harlow Brooks stated that he had seen forty-seven cases of typhoid fever in France and some of them were held for three weeks before a diagnosis could

be made. One of the best articles in the *Bulletin* published for the medical officers in France was on the subject of the anomalous symptoms presented by these patients. In one case ten blood cultures and ten stool cultures were made before it was possible to arrive at a diagnosis. The symptoms were different from those of a typical case of typhoid fever; especially in respect to the typhoid spots and the size of the spleen. He therefore felt there was some excuse for the failure to recognize the condition.

Dr. EMERSON suggested the possibility that the symptoms of typhoid fever had been modified in these atypical cases by vaccination. He knew of several instances in which cases of typhoid fever were not diagnosed because of the unwillingness to accept typhoid fever as a probability in view of the indefinite symptoms present. However, there were a great many records in hospital reports in which the history on review seemed to be typical of typhoid fever. The pathologists were the first to discover the epidemics and this served as an illustration of the possibility of using the results of pathological examination as a warning of the presence of epidemic disease.

SECTION ON MEDICINE.

Stated Meeting, Held December 16, 1919.

DR. CARY EGGLESTON IN THE CHAIR.

Absorbability of Certain Digitalis Principles.—Dr. ROBERT A. HATCHER made this presentation, in which he said that the work was started with the idea of finding a nonproprietary preparation of digitalis suitable for intravenous injection, and in the course of his studies he had become interested in this problem of absorbability of the digitalis bodies. No one appreciated the difficulties encountered in a study of the chemistry of digitalis unless he had actually undertaken such work. Water practically exhausted digitalis, and when the infusion was shaken with chloroform the latter removed certain of the digitalis principles. If the concentrated infusion was mixed with an excess of alcohol a large part of the inert matter was precipitated while all of the active principles remained in the alcoholic solution; if this were evaporated the residue was quite soluble in water, from which a part of the active principles might be removed by shaking with chloroform. The chloroformic extract was soluble in water and the solution appeared to be stable. A saturated solution of this active principle in alcohol was nearly five hundred times as active as the official tincture, and several times as active as a saturated alcoholic solution of digitoxin. The absorbability of the chloroform soluble, and that of the chloroform insoluble fractions from the gastronintestinal tract of the cat was compared roughly by observing the length of time required for emesis to be induced, as vomiting after digitalis was a certain indication of its having been absorbed. There was a difference in digitalis preparations due to a difference in their absorbability. If vomiting occurred after the administration of a preparation of digitalis it furnished pretty good evidence of the absorbability of that preparation. Vomiting occurred more quickly after the administration of the "chloroform soluble" fraction than after the chloroform insoluble preparations. The chloroform soluble fraction of digitalis was so bitter that a 1/1,000,000 dilution with water still retained its bitter taste. He believed this preparation was absorbed more nearly uniformly than preparations made from digitalis derived from widely different sources. The evidence went to show that specimens of digitalis leaves differed widely under different methods of cultivation and different climatic conditions. One got more uniform results from a preparation made from one specimen than from one made from leaves derived from widely different sources. The point to be emphasized was that there was a chloroform soluble fraction of digitalis leaves which was easily absorbed and long acting, and there was a chloroform insoluble fraction briefly acting and rapidly eliminated. He had examined a great many specimens of digitalis, among them one prepared from fluid extract thirty-eight years ago, and used clinically at Bellevue Hospital as recently as eight years ago, at which time it was still active. This went to show that an active preparation of digitalis retained its power for a long time. There was a great difference in the rate of elimination of different digitalis preparations, some being eliminated within a few hours and some continuing to act for two or three weeks. A recent investigator stated that digitoxin was not therapeutically active, and that digitalis grown in the shade contained no digitoxin. It was possible that some of the specimens which were found to contain little of the chloroform soluble fraction might have been grown under such conditions.

Notes on Digitalis Medication: Absorption; Variable Susceptibility; Rate of Disappearance.—Dr. HAROLD E. B. PARDEE read this paper. He stated that certain changes were brought about in the electrographic tracings by the administration of digitalis; one of these changes was in the "T" wave. He had studied these changes in auricular fibrillation, and sinus arrhythmia. Observations were made at varying periods of time after the administration of 10 minims of digitalis. After the end of two hours there was no perceptible effect upon the "T" wave. At the end of four hours there was a slight diminution in the "T" wave; at the end of six hours there was a still further diminution. The maximum effect seemed to be reached about this time. After twenty-four hours the effect was still perceptible. The patients upon whom these observations were made all had sinus arrhythmia except one. In this, a case of auricular fibrillation, they took records at the end of ten minutes and then at the end of every hour, and found that the rate came down from 124 to 109. This rate of absorption seemed to be the same, no matter what disease the patient had, and also when he was normal. It had been shown to be the same in endocarditis, cerebrospinal lues, and nephritis. There seemed to be no difference in the rate of absorption between cardiac and noncardiac cases. A study of the rate of disappearance of digitalis from the body was made in 22 cases. In these subjects the intitial dose was given so that the toxic symptoms appeared in from six to eight days, usually starting with doses of 39 minims of the tincture every four hours, and continuing with 15 or 20 minims every four hours. The second course was usually given in the same way, starting with a large dose and continuing with 20, 15, or even 10 minims, every four hours, three times a day. The second course was completed in an average of six days. The details and results of these observations were tabulated and showed that the average rate of disappearance of the drug from the body was 22 minims of the tincture per day. In half the cases the figure was below this, and in half above it. The rate of disappearance seemed to be independent of the amount of digitalis present in the body at the time, for it did not vary with the number of days elapsing between the first and the second points of toxicity. Nor was any relation noted between variations in the rate of disappearance and either the weight of the patient, the size of the doses of the tincture at the time vomiting occurred, the rapidity of the rate of administration of the total dosage, or the degree of heart failure shown by the patient at the time of the test. Susceptibility of the patients to the drug did not seem to influence the result, either, for the rate of disappearance of the drug bore no relation to the quantity of digitalis per pound which was required to produce the toxic symptoms in the patient's first course. It was evident from the results of these observations that the average figure of 22 minims per day would afford a fairly satisfactory basis for long continued digitalis medication. These results had two important bearings upon the administration of digitalis over long periods of time. They demonstrated the approximate efficacy of the dosage of ten minims of tincture of digitalis twice daily and also a new phase of the variability from one individual to another, in the action of digitalis, a variability in the rate of disappearance from the body. Investigations were also carried out to determine the therapeutic dose of tincture of digitalis, among the results of which three things seemed to demand special mention, namely, the importance of the period of administration was very great, for each day some of the drug was destroyed or excreted from the body; the average amount of the tincture required to produce a full therapeutic or early

toxic effect was found to be in agreement with Eggleston's figures, being 3.3 minims, and the variations from one individual to another were of the same considerable magnitude that he found. The variability of the dose of digitalis for different individuals was of great importance in therapeutics. Taking into consideration that a variability had also been found in the rate of disappearance of the drug from the body it was evident how complicated the problem of digitalis medication must be. Two things, however, were quite plain: when the patient had received enough digitalis for his own special organism he would show one of the early toxic effects, usually nausea or vomiting. If after this he continued nauseated while the drug was being given, it meant that he was receiving too much, that was, an excess over his average daily rate of disappearance. When a patient did not react to a usual dose of digitalis it did not necessarily mean that the digitalis was weak. It was possible that the patient might have a high susceptibility, and might require perhaps 4 or 5 minims per pound body weight instead of the usual 2 or 3 minims. On the other hand the patient might not be able to tolerate the average dose of 3 minims.

Clinical Observations of the Absorption of Digitalis.—Dr. CARY EGGLESTON made a preliminary report upon the clinical investigations of the purified preparations of digitalis which Dr. Hatcher had discussed. He stated that up to the present his investigations had been limited to the determination of the dose of the "absorbable fraction" for man when administered orally, to preliminary observations on the rate and uniformity with which the preparation was absorbed, and to the determination in two instances of the persistence of the action of the drug. The method employed for determining the dose for man was the same as described in detail in the author's earlier paper (*Archives of Int. Med.*, July, 1915). Briefly stated, it consisted of the selection of such cases of heart failure as had not received digitalis in any form for at least two weeks preceding the observations. The patients were kept in bed during the period of observation and were given a diet which remained fairly constant throughout the period of study. In patients with edema the fluid intake was limited to 1000 to 1500 c.c. daily, the actual amount taken daily being measured and recorded. The twenty-four hour quantity of urine was recorded daily. The patient's weight in pounds was taken before the drug was administered and was recorded at intervals thereafter, the lowest reached being used for the final calculations of the amount of digitalis actually required, since this represented the weight without edema. Where possible the effects of rest in bed were determined for several days before the digitalis was administered. When the study of each patient was completed the results were analyzed to determine the following points: 1. The total amount of digitalis required to produce the first demonstrable evidence of action. 2. The total amount of digitalis required to produce full therapeutic effects. 3. The total amount taken up to the time when nausea and emesis appeared. From these data the amount of digitalis required to produce each of these effects was calculated in terms of fractions of a cat unit for each pound of the patient's body weight, the lowest weight reached being used. A cat unit was defined as that weight of the dry drug, expressed in milligrams, which was required to kill one kilogram of cat when injected slowly intravenously. The results of this investigation were shown in tables which were analyzed in detail. In summing up the results of this analysis Dr. Eggleston said that these studies were as yet too few to warrant the drawing of any conclusions, so he merely suggested a few deductions which might probably prove valid. These were: 1. The purified tincture of digitalis did not owe its activity to pure crystalline digitoxin. 2. The dose for man by oral administration was essentially the same as that of high grade galenical preparations of digitalis, when measured in terms of activity on the cat. 3. The purified tincture was probably absorbed more uniformly from the human alimentary canal than were different specimens of the galenical preparations. 4. The persistence of action of the purified tincture was not less than that of pure digitoxin or of the best samples of digitalis. He was now in a position to begin studies on the applicability of this preparation for intravenous administration and hoped to be able to report his results before very long. He also planned to make comparative studies on the oral administration of galenical tinctures, purified tinctures, and the poorly absorbed fraction, all obtained from the same specimens of digitalis leaf.

Dr. GEORGE B. WALLACE congratulated the chairman of the section on having a program of such unusual excellence, and said that Dr. Hatcher's paper had particularly interested him. The fact brought out by Dr. Hatcher that preparations of digitalis which met the pharmacopeial requirement of biological assay might be practically inactive therapeutically because of failure of absorption in the intestines was of great importance. In other words, the guarantee of a preparation standardized according to the pharmacopeial method might be no guarantee at all. The obtaining of an active water soluble, easily absorbable preparation of digitalis was not only of great help in the ordinary form of administration, but enlarged the field of intravenous medication.

Dr. BERNARD S. OPPENHEIMER said he did not feel competent to discuss such a complex subject as digitalis, as he had never done any work with the substance. The determination by Dr. Hatcher of the chloroform soluble, *i.e.* the more readily absorbable, fraction was of great practical interest, as it had explained the recent failure to get the expected therapeutic results with a certain digitalis preparation used at the hospital. This preparation was chosen by the hospital pharmacist as the best fluid extract he could purchase, and, as Dr. Wallace had suggested, it met the biological tests. In private practice he had not had this difficulty with partially inactive preparations, but he was accustomed to prescribing a freshly prepared infusion made by one druggist, or special foreign preparations too expensive for hospital use. He rather disliked doing this, so he hoped that the investigators who are working in this field intensively would give the clinicians information, beginning with the plant, so that active standardized inexpensive preparations of digitalis would be available for hospital use.

Dr. HATCHER, in closing, said it was hardly necessary to emphasize that this purified preparation gave more uniform absorption than when one was using the ordinary preparations. He wished also to say that there was nothing wrong with the manufacturers. The conditions incident to the manufacture of commercial digitalis were such that a poorly absorbable product might result without anybody being to blame. He had used many ways of extracting the digitalis, and it was possible to take the chloroform soluble factor out by immersing the digitalis in water over chloroform for some days. The procedure did not change the digitalis bodies in any way.

Dr. PARDEE, in closing, said he was glad Dr. Eggleston had found so much of interest in these studies. One point he had not emphasized as he should have done and that was that there was a variation in the individual rate of elimination. There was a considerable variation just as in the individual suceptibility and that must be borne in mind in administering digitalis to a patient over a long period of time; if he eliminated rapidly one must give him more than if he eliminated slowly.

Dr. EGGLESTON, in closing, said that the differences in his figures and those of Dr. Pardee were due to the fact that entirely different criteria were employed. The two studies harmonized very perfectly. One point in Dr. Pardee's presentation was particularly interesting to him, and that was that in the table showing the first effects of digitalis these first effects were exceedingly slight at the end of four hours, and reached the maximum in six hours from single doses. With the criteria Dr. Pardee was using he was unquestionably obtaining the whole course of action of that single dose, and he found the average time for the maximum effect to be six hours; that meant the time required for the digitalis to be absorbed and exert its full action on the heart. In Dr. Eggleston's experience he had come to adopt the six-hour interval between doses, and he had reached that interval through entirely different lines. He had come to the conclusion that every dose of digitalis reached its maximum absorption within six hours.

Another point was with reference to the average dose. In the series of experimental cases which Dr. Pardee presented he found the average dose of digitalis to be about 3 minims per pound of body weight. Dr. Eggleston wished to emphasize that that figure happened to be the average in this particular series of cases, and for the particular preparation of digitalis used, and he wished to emphasize the danger of using the full average dose in any patient. While he had published average therapeutic doses he never administered such an average therapeutic dose all at once to a patient. The average dose could usually be given, however, provided it was administered in two, three, or four fractional doses at six-hour intervals. One could then observe the patient at the end of each six-hour interval and see how the patient was reacting to it. That had been his practice, and in the vast majority of cases he found that it took only from ten to sixteen hours to get the average therapeutic effects. It was advisable to start with not more than 50 per cent. of the full calculated dose, even if one was sure the patient had not had any digitalis before, and then one could give the remainder at intervals of six hours. Still another point was that Dr. Pardee had confirmed and amplified his belief that it did not make any difference whether the subject had a cardiac condition or not, he would require approximately the average dose in order to produce a given effect on the heart.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Wednesday, January 14, 1920.

THE PRESIDENT, DR. J. FRANKLIN STAHL, IN THE CHAIR.

Dental Infection in the Production of Nervous and Mental Diseases.—Dr. CHARLES K. MILLS thought it fortunate that the mind of the profession seemed to be trending toward a very healthy discussion of the probable fallacies of dental infection in its relation to various important diseases, and of many other correlated and zealously exploited views. While advancing years might have their drawbacks, they also had their compensations, enabling one through experience to measure the value of many theories of causation and treatment. He referred to the fact that shortly after the death of Colonel Roosevelt a newspaper article appeared which illustrated one of the most dangerous forms of medical propaganda. In this article it was stated that one of Colonel Roosevelt's teeth was the indirect cause of his death. The wholesale statement was further made that thousands of persons died or were incapacitated yearly from maladies arising from infected teeth. The cases of a rescued backward boy whose brain was clouded to the point where he could not master the rudiments of knowledge, and a youth assailed with a lethargy at the age of fifteen, who afterwards became one of the most brilliant of practising lawyers of the Middle West were in this article included in a series of cases supposedly illustrative of the marvelous results of the removal of infected teeth. Dr. Mills said he had but little doubt that literally bushels of teeth of excellent quality had been sacrificed throughout the land as the result of this atrocious article about Colonel Roosevelt. In studying *x*-ray pictures Dr. Mills had been skeptical as to what were called abscesses at the roots of teeth. It had always seemed to him that these pictures represented absorptive lacunæ or artefacts of some other description rather than true abscesses. The roentgen ray enabled one to discriminate between areas of differing density. In a strict sense an abscess could not be demonstrated by a roentgenological investigation. A score or more of cases had come to his knowledge in which important mental and nervous diseases had been attributed to dental infection and in which the teeth had been removed with results in some instances so harmful as to impress one with the almost criminality of the procedure. A few such cases were cited. Dr. Cotton, one of the leading psychiatrists of the country, had attributed many and divers forms of insanity to dental infection. The late Dr. August Hoch in a critical review of one of Dr. Cotton's articles clearly pointed out the logical defects in the presentation. Under the influence of the propaganda of focal infection, Dr. Mills said, to use the expression of his facetious, but learned friend, Dr. Peterson, the colons of epileptics bade fair to be reduced to semicolons by operation. The appendix would soon be no longer left as a vestigial illustration, and the tonsil, protrusive and submerged, was sharing the fate in recent years of the ovary in the early experience of the profession. A nose and throat specialist not long ago had gravely informed Dr. Mills that he thought of preparing a statute to be presented to the state legislature making compulsory the extirpation of the tonsils of children after reaching a certain age on the theory that prevention was better than cure. Why on the same principle might the exodontist friends not be called in for their exterminating activities and free the rising generation of teeth which in the process of time might have their roots infected and abscessed? Dr. Mills would fain protest against the too free use of the therapeutics of organic mutilation. If the craze for violent removal proceeded it would come to pass that there would result a gutless, glandless, toothless, and, he was not sure, thanks to psychology and surgery, a witless race.

Dental Therapeutics Based on Clinical and Roentgen Ray Investigations.—Dr. WILLIAM MIDDLETON FINE expressed his conviction that too many teeth were extracted in the expectation that their removal would cure systemic disturbance. Because it was possible to demonstrate the same microorganisms in pulpless teeth and in arthritic joints it did not necessarily follow that the teeth were invariably the primary cause of the infection. The extraction of badly decayed teeth upon whose roots were abscesses, or their restoration to health and usefulness, removed one of the contributing factors in the cause and development of many diseases. He did not share the belief, however, that all non-vital teeth should be removed. The bodily protective processes prevented well treated teeth without living pulps being the direct cause of disease. Medical literature indicated that arthritis was produced by a constipative diet. Cases with teeth loose in the gums accompanied with bleeding gums and pus had cleared up when the pathological conditions in the intestinal tract were removed. The statements of Talbot would lead one to believe that not all the shadows seen on radiographs of dead teeth were abscesses and contained pus, and therefore that these teeth should not be ruthlessly extracted. Particularly did he wish to emphasize the fact of his entire accord with those of the profession who advised the extraction of dead and diseased teeth after a thorough attempt to cure had failed, or was in doubt. It was more than likely that seventy-five per cent. of the shadows in the radiographs at the apical ends of teeth had been caused by irritation from the mechanical treatment and drugs in dental operations and that the teeth were unjustifiably removed. He had seen teeth that under the *x*-ray examination produced shadows, indicating what some were pleased to call abscesses, remain for fifteen years or longer without pus or any symptom of disease. It seemed to him that about 80 per cent. of the bodily ills arose from the improper functioning of stomach, intestines, liver, and kidneys. He believed there was once a time when all the bodily ills were fastened upon the appendix. Nowadays the statement was made: "Let's call it the teeth and practise exodontistry." Since starting to write this paper he had had three cards from men announcing that they were giving up general dental practice to go into the extraction of teeth. Three new extractors every week, in his opinion, were not needed. The examination of a patient for an obscure cause of systemic disturbance should be made by physician, radiographer, bacteriologist, and dentist.

The Present Status of Oral Sepsis in Relation to Systemic Disease.—Dr. JAMES M. ANDERS said that the importance of the relation of tooth-root infection to systemic diseases could not be overstressed from the viewpoint of study and investigation. Present knowledge of the flora of the mouth as related to special affections was still imperfect. A closer cooperation between dentist and physician along bacteriological lines was urgently needed to intelligently deal with affections of the teeth and alveolar processes and to correct

the haphazard sacrifice of the masticating apparatus. The writer recalled a case of epilepsy in a young woman of 19 in which upon the advice of a physician all the teeth, though in good condition, were extracted, without, of course, any effect upon the epilepsy. It behooved medical and dental bodies to oppose the appalling present rate of removal of dental organs. It has been shown that after the fortieth year of life disseminated infections leading to constitutional disturbances are more frequent and of more serious character than in younger subjects. That many morbid medical conditions might be of oral origin was shown in their cure following the removal of the foci of oral infection. Among such medical conditions were arthritis, endocarditis, pericarditis, myocarditis, gastritis, myocardial degeneration, chronic nephritis, exophthalmic goiter, and many others. Gingival and dental conditions, however, were rarely the sole cause of the morbid states for which they might be held responsible. Before teeth were condemned it was a matter of vital importance to determine that other than oral infectious foci were not present. Treatment based upon *x*-ray studies alone was unwise, since the deeper dental lesions might be simulated by other local conditions, and an abscess which actually existed might not be shown. The local and clinical features were to be carefully studied, and extreme caution should be observed in ascribing a systemic infection to the mouth condition. Bacteriological study in oral infections was regarded as essential. The prevention of tooth-root disease should be preeminent in the minds of all interested in the welfare of the race. Fones was quoted as saying, "We know of no one movement from the health standpoint that would be more beneficial to the nation at large than a serious educational campaign to eliminate dental caries so far as would be possible. Sanitary oral cavities are potent factors in limiting the incidence and spread of communicable diseases."

Roentgen Ray Studies of Dental Defects. — Dr. HENRY K. PANCOAST showed Roentgen ray slides of dental conditions and spoke of the value of this means of study of the oral cavity, believing that when properly carried out it offered the best method in a large number of cases. The roentgenologist, however, was not able to judge of the direct connection between dental conditions and their supposedly resultant systemic conditions. This was the work of the internist. He was perfectly frank to say that not all "clear areas" were due to abscesses at the roots of teeth. Some might be due to infections of the past, others to chemical irritants. If properly read, however, most of these "clear areas" indicated the presence of active abscesses. He was absolutely opposed to the wholesale extraction of teeth. In many instances it was possible to treat abscessed teeth successfully and have good service from these teeth afterwards. He referred to one instance in which an abscess at the root of a tooth did not show in the film, but such occurrences, he said, were rare. Experience in the interpretation of the films was more important than the technique, and such interpretation was best carried out by the dentist and the roentgenologist in conjunction.

Physiological Action of Extract of Tonsil.—Farmachidis has found in experiment an analogy between the actions of pancreatic and tonsillar extracts.—*La Presse Médicale.*

A Special Strain of Spirochete the Cause of Paresis.—Marie and Levaditi inoculated rabbits with chancre virus in one region and blood of general paresis in another, and watched the incubation, etc. The impression was that two different strains of treponema were involved.—*Le Progrès Médical.*

Rupture of the Aorta.—Devic and Lamy report the case of a man of 53 without suggestion of syphilis who complained of violent abdominal and lumbar pains. His vascular apparatus seemed quite intact and there were no evidences of tabes. Lumbar puncture showed that the cerebrospinal fluid was present under high pressure with a lymphocytosis. The severe pains were present off and on for three weeks, when death took place suddenly in the night. Autopsy showed rupture of the abdominal aorta which was also the seat of numerous atheromatous placques.—*La Presse Médicale.*

THE MEASURES OF INTELLIGENCE DIAGNOSTICALLY REMEASURED.

BY J. VICTOR HABERMAN, A.B., M.D., M.S.D.,

NEW YORK.

IN this Fourth Report[1, 2, 3] of our studies on examining the mind of the child or adolescent, we shall take up the individual tests employed as measures of intelligence, following the sequence of our own arrangement of the tests chosen from Binet, Bobertag, De Sanctis, Ebbinghaus, Meumann, Ranschburg, Rossolimo, Terman, Yerkes, Ziehen, etc., to be applied in a detail-inspection of intelligence which should prove a differentiating or *diagnostic examination method.* Our grounds and discussion for, and insistence on, such a diagnostic procedure, as well as an extended criticism of the present examining methods, especially the Binet "averaging of the general intelligence" (and its revisions), will be found in our second report.[2] An exposition of the *intelligence problem* as a whole will also be found there, the issue between intelligence factors and psychopathy drawn, and finally the evolvement of this diagnostic examining method explained.

In order to follow our "faculty" divisions, our group arrangement of tests, and make this procedure clear, let me again define the *process* or series of phenomena involved in what we term *intelligence.* This process is inaugurated by the *attention,* which initials all conscious notation, for attention must hold strong and steadily enough if anything is to be cortically infixed and retained (remembered). We may attend cursorily or concentratedly, with intent of infixing for the moment only (immediate recall), or for a longer period (deferred recall), or for permanence (permanent recall—i.e., *knowledge*), intention expressing itself in the degree and intensity of attention. The infixing is accompanied by, or rather accomplished through, *association.* That is, in the act of registering the new incoming impressions, things are matched up, associated and differentiated in mind—like things being added to things (concepts) of like kind already there. Never does anything come isolated, or remain detached, within the mind; always is the incoming matter added to something—in reality, to accumulations of earlier memory depositions. In this way the new or unfamiliar encountered in our mental life is gone over, sifted, arranged, compiled and tagged. And once posited—remembered—it forms part of our knowledge: that is, the sum total or aggregate of these memory-depositions comprises our *knowledge.*

But how do we accomplish the sifting, arranging, tagging? We do this with the knowledge already possessed—the old "apperception mass" (better the modern "association play")—with which we analyze, collate, compare and contrast. In a simple way this mental process already takes place in the young child. As it grows older, however, the child no longer compares and contrasts grossly, it distinguishes elemental parts from a whole—as whiteness, sweetness, hardness, etc., from the concept sugar; whiteness, coldness, softness, etc., from the concept snow—compares these, analyses and synthesizes, and hence differentiates both, knows both. Or again, it spies out similarities in series of varied objects—the little sparrow, the larger goose and duck, the stately peacock, all differing in size, color, actions, but all having beaks and wings and able to fly: hence, birds—and so generalizes and abstracts. This procedure, all in all, we term *comprehension.* Knowledge, therefore, on the one hand aids in comprehension and understanding; on the other, through analysis, through differentiation and remembering differences, our knowledge grows.

Lastly—and this is the highest of all mental functions, maturing late in the child—we possess the ability to combine our "knowledge elements," our concepts or part-concepts, or, of first unloosing or severing associations already registered in mind and recombining them—or indeed, of seeking rare, as yet un-knowledged elements and forging new association chains, begetting entities comparatively singular, unique. This faculty we term *combination.* Through such ability we can apply a fitting completion when but a part is given in a train of thought, or span gaps where links are missing. Thus we orient ourselves in time and place, adequately meet new situations, bring about logical synthesis in our thinking, discern meaning and motive in the composite of picture, story or action, sift cause and effect, exercise critique, judge, plan, reason, presage—imagine, conceive and create.

In this *intelligence process,* attention and memory are essential primary functions without which there could be little comprehension or combination. It is through them that the normal mind accumulates, retains and recalls—the poor mind, the average mind, the exceptionally endowed. Though part and parcel of the total activity we term intelligence, they may nevertheless be segmented from the functions of *comprehension* and *combination* and accounted fundamentals, the latter being superstructures, especial or qualitative faculties, if we may put it so, the one the comparative, the other the superlative of mind. It might be well to remember this, as in the literature confusion is often invited

by one author including the entire sequence of phenomena in his conception of intelligence, another having only the higher faculties in view. It is on this point that definitions of intelligence go astray. In reality, the fundamentals vie equally in importance with the higher faculties, and *all* must be probed in a rational examination of intelligence. In other words, when we speak of intelligence, we should imply all functions mentioned, *attention, memory, comprehension,* and *combination.* However, it is true that that something which gives one individual mental superiority over another, which makes us designate one individual as *more intelligent,* more intellectual, than another, that something, though occasionally due to exceptional powers of memory and attention, occasionally to sharper comprehension, that something is for the most part based upon superior combinational ability. One might speak of the "intelligence process" and the "intelligence endowment" or just of "intelligence" versus "endowment" (Begabung). At all events, one must signify the particular conception one means to imply.

To investigate, quantitatively and qualitatively, this intelligence process, we have listed the functions or faculties just outlined under a series of captions on our test sheet, namely: 1. Attention. 2. *Memory.* 3. Knowledge. 4. *Comprehension.* 5. *Combination.* 6. Feeling.

Strictly speaking, *attention* is really not a factor of intelligence parallelable to memory, comprehension, and combination; nevertheless, it is so closely involved in the intelligence process as to be inseparable from it. As we have said, it is the inaugurating and likewise the stabilizing phenomenon, and one that must be normal if the examination results of 2, 3, 4, and 5 are to be taken on their face value. If found abnormal, then the examination results must be interpreted, for the deviations and shortcomings *may* then be due to psychopathy (incurring abnormal attention) and not necessarily to intelligence defect. That is, you may find poor or abnormal attention in the psychopathic with sound intelligence, as well as in the defective or feebleminded.

As to *knowledge,* it is a matter of memory, *i.e.,* permanent memories. Its examination, however, entails a mechanism and problem differing somewhat from the examination of immediate and mediate memory. It is, therefore, rubriced separately on our sheet. The convenience and *rational* of this will be more evident when we come to discuss knowledge.

Feeling, which we have added as a sixth caption, does not belong among the intelligence functions, and its abnormalities fall entirely in the sphere of psychopathy. It has a strong effect upon the association process, however, and may, therefore, decidedly influence ideation and invalidate our intelligence examination. As in the matter of attention, it must be found normal if the examination results are to be taken on their face value. A brief investigation of feeling should therefore be undertaken with every intelligence examination. And indeed but a few questions are often sufficient to bring out the normal or abnormal affectivity of an individual, or show up the possible or potential presence of psychopathy.*

To test out these functions, series of tests have been assembled under each rubric, tests selected from various sources as the most valuable for the purpose.

A special "Intelligence-test-sheet" has been drawn up, the group-arrangement being according to "faculties" (the above captions) instead of age headings, as in the case of the Binet and Terman methods. Age-norm indices, however, are supplied to the right of the tests and the tests arranged in gradations of difficulty. Standardization wherever possible is insisted on, only our norms will be found more elastic, our study of the individual tests showing clearly that the sharp demarcations of the Binet and revised Binet methods are exaggerations often verging on fallacy.

In our earliest presentation,[4, 5] the tests for all the years were placed on one sheet. It has been found more advantageous (and a less cumbersome procedure) to have the tests for three or four consecutive years on a single sheet, thus the tests for the 3d, 4th, and 5th, the 6th, 7th, and 8th, and the 9th, 10th, and 12th years separately. However, this arrangement in no way alters the method.

The results of the examination of the six facultative groups are not to be averaged in an I. Q., as such, remembering the asymmetries of endowment and the disproportionalities in mental deficiency or defect, we believe is a misnomer, no real averaging of the mental faculties being possible, at least, not when accurate insight or diagnostic introspection is at stake. Instead, the results will be schematically presented as a *curve* or psychograph, somewhat, though not precisely, similar to the "profile" of Rossolimo[6], or a "reading" in the manner of the electrocardiogram. Here the complete examination may be viewed and comprehended as an aggregate, as well as surveyed in terms of its individual details. That this may also be computed in figures is, of course, not impossible.*

The individual tests which are now to be taken up will be studied from the viewpoints of their value as tests of the function to be tested, of their special applicability to chronological periods (*i.e.* their age-standardization), and particularly their diagnostic value, that is, whether they are to be deemed *intelligence-diagnostic* when passed (no defective being able to pass such a test), *defect-diagnostic* where failed in (no really intelligent child failing in such a test). From the fashion of averaging Binet and Terman tests, one might assume that all such tests were of equal valence. Yet nothing comes less near the truth. Some tests mean little or nothing when passed, some little or nothing where flunked. Some again have decided value *only* if passed, others *only* if not passed. Some are qualitative, rather than quantitative tests. Finally, some tests have characteristic value in differentiating higher and lower endowment (within normality), others in differentiating various grades of defect, a few in giving demarcations between the poorest (lowest) grades of normality and the mild-

*Too much importance cannot be placed upon this search in all examinations of the child's mind, whether for the testing of intelligence or the diagnosis of functional neuroses, character abnormalities, or outspoken psychopathy. To this purpose a special anamnestic sheet has been prepared so devised as to bring out the possible (*and pertinent*) abnormalities in the heredity, during parturition, in the child's infancy, in childhood, and adolescence. The data gathered through this anamnestic inquiry should always be compared with the results of the examination of Feeling. These anamnestic blanks, together with our intelligence sheets, are procurable from the Fetzer Press, 62 Reade Street, New York City.

*Rossolimo himself attempts this.

est grade of defect. All this will presently be made evident.*

Our last Report† having been on Memory, we shall stray somewhat from the arranged order and begin our study with *the tests of memory.*

NAME..... DIAGNOSIS (CLINICAL).....
ADDRESS..... DIAGNOSIS (PSYCHOLOGICAL).....
AGE.....SCHOOL GRADE..... MENTAL AGE.....
DATE.....EXAMINER..... TEACHER'S RATING.....

(*Tests at 6-7-8 Years of Age*)

1. KNOWLEDGE:
(a) Things in a room: chair, table, sofa, bed, pictures. At 6
(b) Table things: spoon, fork, knife, plate, cup. 6
*(c) Things on the street: horse, store, wagon, auto, car, policeman, solder, train, trees, flowers. (At 6-7).
(d) Winter, Spring, Summer, Fall, Christmas. 6-7
("When does one go sleighing? the grass grow? leaves fall?" etc.)
(e) Colors: *names* R. B. G. Y. 5-6-7
Recognizes R. B. G. Y. W. Blk. (at 4-6), Br. Gr. V. P. Or. (At 5-6).
*Knows colors: of grass, milk, blood, sky, coal, leaves, butter, strawberry. (At 5-6).
*(f) Forms: of wheel, box, top, stamp, penny, door, ball. (At 5-6).
(Use cardboard with silhouettes.)
(g) Money: names nickle, penny, quarter, dime. 6-7
Names six coins (dollar, half-dollar). 7-8
(h) Days of the week (beginning with Tuesday). 7-8
(i) Reads and writes (elementary)

2. MEMORY:
I. Send child on make-believe errand for 3 purchases @ 5c, 15c & 8c.
(a) II. Repeats 4 digits (at 4; but no more than 4 at 6) 6
Repeats 5 digits (53926-71852-94638) (1 out of 3 series). 7
(b) III. *Recalls* purchases.
*(c) Paired-associates 5.10.15. *R.t.*: Deferred 24 h. *R.t.*:
(d) Repeats sentences of 14-18 syl. (at 6), 16-18 or 20 syl. (at 7). Etc. 6-7
I. Span: syl. II. Sensible and senseless errors:
(e) Repeats story No. 1.
(f) Carries out commissions. (3 at 5)
(g) Copies a triangle (with autocriticism). Expose 15", cover 15". 6-
Copies a diamond. 6-7-
*(h) Learning test: repetitions. Relearning: repetitions. Saving: %

(i) Reliability of memory: (Qualitative test).
I. Story No. 1: II. Picture No. 1: III. Exposure test:
IV. Suggestibility:

3. COMPREHENSION:
(a) Numbers: counts 13 pennies or marbles. 6
*Adds 3+1, 3+2, 3+5 pennies. (At 8.)
(b) Defines in terms of use: 5-6
Defines per description or class name: 8-9
(fork, chair, hammer, cake, doll, wagon, horse, soldier, penny, rose).
Spontaneously: Per example:
(c) Relations: I larger-smaller, nearest-most distant. 6-7
II. Divides a line of 2 cm. into longer and shorter parts; into half. 6-7
(d) Directions: right-left (at 6-7); front-back; above-below. 6
*(e) Forms: flat (at 4); solid (ball, cube, pyramid, prisms) (At 5-6.)
(f) Weights: I. arranges (2 at 5.....5 at 9 or 10)
*II. balance test (at 7 and after)
(g) Pictures: describes (picture No. 1) 6-7
(h) I. Differentiates and II. gives similarities:
fly-butterfly; wood-glass; paper-cloth. 7-8
glass-ice; streetcar-train; sun-moon. 8-9

(i) Ethical ideas: "Which is worse, a mistake or a lie? to borrow or steal? (Then give 3 examples and ask whether mistake or lie.) 7-8

The Tests for Memory Examination

In this group of tests we keep in mind the memory phenomena already alluded to.† Our tests cover the examination of *immediate recall* [of digits, test (a)*; of associates, test (c); of syllables (sentences), test (d); of context of story, test (e); of commissions, test (f)], and *mediate* or *deferred recall* [of purchases, test (b); of associates, test (c); of copying designs, test (g); of retelling story and also re-describing picture, test (i)]. The tests for *permanent recall* will be taken up under Knowledge.

PHYSICAL STATUS..... UNDERSTANDING:
Fatigue?
MENTAL ATTITUDE (AND EASE)..... AGILITY, DEXTERITY.....
Inhibited?
SENSES: S.H.T. SM..... MECHANICAL SENSE.....
SPEECH.....LANGUAGE ABILITY.....

4. COMBINATION:
(a) Orientation: time (morning or afternoon, season). At 6

*(b) Part-picture recognition. (At 6.)
(c) Picture lacking eyes, nose, etc. 6-7
*(d) Grasps situation of elementary pictures. (At 6.)
I. Boy caught in the rain. II. Boy's hat being blown away.
III. Tumbling from sled.
(Ask in each case, "What should he have done?")
(e) Grasps point of pictures: 1, 2, 3, 4 (with the aid of questions). 8-9
(f) Grasps point of simple story, No. 1 at 7. 7
(I. Ask "Why did she get all this money?" II. "Why is the story told?")
(g) Problems in judgment: 8
I. "If you were going away and missed your train, what would you do?"
II. "What ought you to do if you broke something belonging to someone else?"
III. "What would you do if you found, when on your way to school, that you were late?"
*(h) Judgment through observation: (At 8-9.)
I. "Do large things weigh more or less than small ones?"
II. "How is it that a small thing sometimes weighs more than a larger?"
III. "Do distant things appear larger or smaller than near ones?"
IV. "Do distant things only look smaller, or are they smaller?"

*(i) Two words into logical sentence (*oral*). Qualitative test (*give example*). Snow-melts; teacher-pleased; tree-leaves.

5. ATTENTION:
(a) Attention paid to things shown in the room; to the pictures shown; to the tests given.
(b) Repeats in reversed order: 385; 724; 691. [4 digits at 9.] 7
Gives days of week in reversed order. 8
(c) Counts from 20 to 1. 8
*(d) Assortment test (of 100 seeds—ten varieties of 10 each). Time.
(e) Note outcome of test 2. (a), digits test, and (d), sentence span.

6. FEELING:
(a) Aesthetic choosing, 1, 2, 3. 5-6
(b) "What good deed have you ever done?" 6-7
(c) "A sparrow had a nest....." 6-7
(d) Give examples of cruelty, joy, want, and ask if sad, joyous, etc.
(e) Note from history if cruel to animals or playmates; if affectionate at home; if pleased with music, perfume, sweets.

Test (a)—digits test: After being told to listen carefully—this to get its attention—the child is given a set of digits and asked to repeat them one after the other. The digits are given without rhythm, and given but once. First try 4, then 5, etc. (5392 6—7185 2—9463 8).† At *six* years 4 digits should be retained; at *seven* years, 5—the test being standardized for one correct series out of three to pass.

Binet originally required 2 digits at *three*, 3 digits at *four*, and 5 digits at *seven*. In the 1911 revision the 5 digits test was placed in the *eighth* year. In these tests but one correct answer out of three series was required to pass. The test was not given at *six*. Terman‡ requires 3 digits at *three*, 4 at *four* (which test was passed by about three-fourths of his four-year-olds), 5 at *seven* (one correct of three series) and 6 at *ten* (one correct of two series). Bobertag‡‡ in his tryout found that 4

*Though not yet especially indicated on our present *test-sheet*, it will be quite feasible through the use of "reference marks" to use our test series for various purposes, thus (1) for the *diagnostic intelligence examination*, in which all the groups are tested out (this always indicated in mental examinations, in examinations to ascertain the presence or possible presence of deficiency or defect, in cases where the mentality in general is to be analyzed, for pedagogical analyses, etc.); (2) for the examination of *special endowment*, in which case only a series of specially marked tests—chiefly comprehension and combinational tests—are applied. This type of test will be sufficient for the *rating* of superior children, or to sort out the superior from the average in groups of normal intelligent children; (3) for special examination, such as quality types among the intelligent (the poetic, fantasy type, the practical, etc.), or in examining delinquents (tests of report, of ethical sense, etc.), etc.

†For a detailed study of the memory phenomena see our Third Report.[3]

*This likewise is a test of attention, *i.e.*, attention-span (note later comment under Attention).

†Bobertag uses the following: 51942, 64853, 93718; Terman uses 4739, 2854, 7261, 31759, 42385, 98176. Our own digits have been carefully selected. In the six digits test Terman uses 374859 and 521746; Bobertag, 250841, 573916, 095827.

‡Bobertag points out that care should be taken not to disconcert the child by looking at him while he answers.

digits were correctly given at *five* in 85 per cent. of his cases—a little too easy, therefore, for the *fifth* year—5 digits by 42 per cent. at *six*, and by 77 per cent. at *seven*. (At *eight* 92 per cent. gave 5 digits, and 53 per cent. gave 6. At *nine* only 54 per cent. passed 6, but 82 per cent. at *ten*. Hence, 6 digits is too difficult a test for even the ninth year and belongs in the *tenth*.) Goddard keeps the tests as in the Binet revision.

Considering these statistics, we would require to pass (*one correct series out of three*):

(1) 3 to 4 digits at *four*
(2) 4 digits at *five*
(3) 4 digits at *six*
(4) 5 digits at *seven*
(5) 5 digits at *eight*
(6) 5 digits at *nine*
(7) 6 digits at *ten*

But according to Bobertag's study

(2) 4 digits at *five* is passed by 85%
5 digits at *six* is passed by 42%
(4) 5 digits at *seven* is passed by 77%
(5) 5 digits at *eight* is passed by 92%
6 digits at *eight* is passed by 53%*
(7) 6 digits at *ten* is passed by 82%

Hence, (2), (4), (5), and (7) are too easy, while almost half gave 5 digits at *six* and more than half gave 6 at *eight*.

What, one might ask, would the statistics be if *two* out of three series (rather than one out of two) were demanded to pass instead of one out of three? Bearing the above figures in mind, could one probably correctly demand

4 digits at *five*
5 digits at *seven*, surely at *eight*
6 digits at *ten*

requiring two correct series out of three?‡

Norms given above the tenth year are:

7 digits, one of three trials, at 15 (Binet†)
7 digits, one of three trials, at 12 (Goddard)
7 digits, one of two trials, at 14 (Terman)
8 digits, one of three trials, superior adult (Terman)
6-9 digits, ? of ? trials, at 12 (Meumann)
6-10 digits, ? of ? trials, at 14 (Meumann)

Bobertag's suggestion of asking the child for a criticism of its performance is a rather good one. He asks, "Did you repeat the numbers correctly?" Of course, some children will say "Yes" without being sure; but Bobertag believes it a good sign if a child is not so certain it has given a correct answer. Quite the contrary is the case when the child who has done poorly maintains it has done well.

What is the importance of this test? It is a test of *memory-span* and of immediate recall. It depends on age rather than upon intelligence; that is, an older child has a better memory-span for immediate recall than a younger child, and the span-ability grows from year to year.** However, there is a correlation with average intelligence. (See comment in test of sentences; Cf., also the article on Memory¶.)

*Jacobs, however, got 6.6 digits as his average for the *eighth* year (but the numbers tested were very few), 6.7 at *nine*, 6.8 at *ten*. (Cited by Whipple, p. 538).

†Terman, in his first alternative test at ten, asks for 6 digits, requiring one correct of two series.

‡This brings up the point as to how many correct answers shall be required out of a series of trials to pass a test. Occasionally one finds 1 out of 3 required, elsewhere 1 of 2, again 2 of 3. Terman, for instance, requires 1 correct of 3 series in the digits test at three, four and seven, but 1 correct of two trials at ten and fourteen. It would appear that a 1 out of 2 trials test hazards the element of chance, and that 2 of 3 trials ought really *always* be required, while 3 of 5 would be even safer. If we were to rate a child throughout on its *highest possible* attainment, we would no doubt get a different estimate than when examining for its *general average* attainment in all tests. The latter is the method upon which the teacher's (school) rating is based—and it seems no more than sound that this should be the method in intelligence examinations. Possibly one might note both the maximum and the average accomplishment, and get some interesting data in this way.

Binet originally required 7 digits in the twelfth year, later placing the test in the fifteenth. Terman found the test too easy for the fourteenth year, if three series are given, and therefore (as an alternative test in the fourteenth year) exacts 1 correct of 2 series (2183439, 9728475). Bobertag found that but a fourth of his children at 12 could give 7 digits and states that the test is much too difficult, and that without previous practice many adults are not capable of passing it. Goddard, however, keeps the test at 12. Bobertag's 7 digits series are 9640518, 7384261, 5928037.

**According to Bourdon, up to the fourteenth year. According to Ebbinghaus, up to about fifteen (full physical development), after which it remains constant for some twenty years. Cf. No. 22, p. 464.

¶His memory for *deferred* recall was also phenomenal. At the end of an hour's performance, as well as on the following day, he could repeat all the mathematical operations gone through, even though some three hundred digits had been employed.

A different method of giving the digits test is described by Vieregge (Prüfüng der Merkfähigkeit Gesunder und Geisteskranke mit einfachen Zahlen," Alg. *Zeit., f. Psych.*, 1908 Bd. lxv). A series of digits was (acoustically) given, thus 6.9.3.5., the test person having to combine the numbers into a whole, *i.e.* "six thousand nine hundred and thirty-five." V. first offered 12 numbers to the test person, and, if this was not grasped, then eleven, and so on, until the span was not too large to be retained. (This is the opposite procedure from that in which the digits test is usually given.) Two correct series had to be answered, preferably two following each other, out of a series of 5 to 10. The immediate recall (A) was tested, then (B) deferred recall after one minute without diverting the attention, then (C) with diversion of attention, *i.e.* the test person counting from 99 backwards to 1. The average number of digits recalled in this fashion testing with normal *adults* was:

	A.	B.	C.
Educated normals	7.0	7.3	4.4
Uneducated normals	5.8	5.5	2.3

This considerable difference between C and A must be borne in mind.

Occasionally, or rather, rarely, one comes upon phenomenal *number* memories. Thus Inaudi, who gave public performances of his skill, was able to repeat 42 digits correctly! (the limit for normal adults probably does not exceed 13.)¶ He could not, however, repeat more than 6 or 7 disconnected letters, nor more than a few words of a poem. His memory for colors, forms, and musical compositions was below average. He was quite illiterate up to 14, yet at 7 was able to multiply mentally two numbers of 5 figures each. His memory was of the auditory type, really auditory-motor, differing in this from most mathematical geniuses and phenomenal calculators, who are usually distinctly visual in type, and can clearly *see* the numbers before them. (See Binet's "Psychologie des grands calculateurs et joueurs d'echecs," Paris, 1894, also Moebius' "Uber die Anlage zur Mathematik," Leipzig, Bart, 1900.) Many such stage "calculators" have shown distinct signs of feeble-mindedness. This does not mean, however, that men with great number memories or mathematicians are all one-sided in their endowment or need be feeble-minded. It is an interesting fact, however, that the

feeble-minded can show up phenomenal memories for immediate recall, and also automatic combination ability for numbers, or at times permanent infixing ability for masses of verbatim material (songs, prayers, Bible passages, etc.), of which they understood not a word. Platezek tells of a legal case in which the evidence offered by a girl was challenged, the school principal and the girl's teacher proclaiming her feebleminded. This girl, when tested with a picture containing 76 details, was able to recall 74 of them, showing an amazing hypernormal infixing ability. (Zur forensischen Bedeutung des Merkfähigkeitsgrades, *Monat f. Kriminalpsychol.*, 1909—Reprint).

Test (b)—Ziehen's test of deferred recall: Previous to giving test (a) one tells the child one is going to send it, *in make believe fashion*, to the store to get certain things—"a loaf of bread for 5 cents, a half pound of butter for 15 cents, and some cheese for 8 cents." This is told just once, and the child instructed, "Now remember what you are to buy."* The problem is to be fixed in mind, the *recall* to be deferred while the attention is diverted to another test—namely, test (a). One then gives test (a) and at the conclusion of it asks the child to *recall* the purchases to be made at the store. (Cf. Vieregge's test C).

This test has not been standardized for separate ages, so that one cannot precisely say how many purchases a child should be able to carry in mind. But this is really not necessary, for the test is not of *how much* a child can carry for deferred recall, but merely whether memory depositions will last for a time despite distraction, attention being meanwhile intensely engaged. However, judging from the usual Binet test of commissions (3 at *five*) and our own experience with this test, three purchases should not be too difficult to carry at the age of six. At least two of the purchases should be recalled at *six* (and all three at *seven*).

The importance of this test lies in the fact that some individuals may have an invalidated memory even though making a good showing with immediate recall tests. Or, in other words, the usual infixing tests give no evidence as to the durability of the impression made. Thus Ziehen pointed out[10] that certain mental patients may carry a series of digits correctly—the infixing process being often quite excellent (a Korsakoff patient, for instance, repeating 6 or even 7 digits)—but who cannot hold a problem for even a few seconds if attention is diverted. In feebleminded or even debile children the same has been noticed. Here we sometimes come upon automatic memories, the child being able to repeat anything in parrot-like fashion—without comprehension, of course—but who cannot defer recall for even the briefest time. It should, however, be remembered that even in normal individuals there may be marked difference in the infixing and retention powers.†

Should there be any doubt whatsoever as to the ability to defer recall, the test is given again—making use of other purchases. (Cf., also test C: paired-associates, deferred 24 hours.)

Test (c)—paired associates: This test belongs to the less definite of our series and is therefore preceded by an asterisk. It has value not so much in its applicability in testing the normal child as in differentiating the meagerly endowed yet normal child from the one mildly defective. This differentiation is often very difficult indeed and this test may therefore prove extremely useful.

Pairs of associated words—in series of five, ten or fifteen—are given (pronounced but once*), the test-person repeating each pair as heard. Then one again starts from the beginning, giving only the first word of each pair, the test-person supplying the associate. One computes the percentage of correct hits and also the *reaction time* (the time taken to supply the associate). Here infixing for immediate recall is tested. One may go through the same series on the following day (24 hours after), again giving merely the first word of each pair. In the latter procedure *deferred recall* is tested, and its average reaction time has been found of more importance than that computed with immediate recall.

The following series of substantives and adjectives is suggested by Ziehen[11] (the arrangement here, however, being slightly altered).

Garden—large	Dress—clean
Tree—green	Table—round
House—small	Flower—red
Bed—warm	River—deep
Room—high	Picture—pretty

This list may be lengthened by an additional five pairs—these being also a little more difficult:

Glass—water
Kitchen—dishes
Steam—kettle
Wood—fire
Steps—cellar

Ranschburg[12], who introduced the reaction-time element, undertook a most elaborate study of this test.† On the results of his examinations of 110 normal children between the ages of 6 to 19, and 37 abnormal ones between the ages of 7 to 16, he concludes the following:

Concerning correct hits: In the normal child one will expect 75 per cent. of correct hits, or over. In the pathologically deficient, however (i.e. the milder grade of defective), immediate recall need by no means be poor—the average result being in fact but 20 per cent. smaller than in the normals. Results under 50 per cent. from the school age up argue against good endowment. Results under 25 per cent. argue with great probability for pathological deficiency. The test, then, for correct hits and these immediately recalled is of no particular importance.

The test being applied for 24 hours *deferred recall* proved more valuable. Here results under 50 per cent. at ages between 6 and 11 spoke probably

*This is to get the child's attention and *will to remember*. Ziehen himself applies the test somewhat differently. He gives one or two easy multiplication examples, instead of the purchase commissions, without telling the child to remember them, or that he will later ask for them. In children distraction of attention is so liable that it seems safer to follow in our above manner.

†In the Binet tests, as well as in the Terman and Yerkes series, tests of deferred memory are conspicuous by their absence.

*In testing defectives and psychopathic children one may have to give the series twice or even thrice if not retained on one presentation. (On this point see No. 3, part 3.)

†Strange to say, R. does not give the lists of paired associates which he used for his studies. One such list, however (p. 135), is as follows: Coffin—body; number—digits; load—bother; tone—voice; ball—mask; act—drama; ice—glacier; thing—matter.

from 14:1 against normality and with probability of 8.5:1 for pathological deficiency.

Concerning reaction time in general, slow reproduction argued against an averagingly good endowment.* The reverse, however, was not true, rapid reproduction did not point to especially good endowment.

In normals between 6 and 11 the average reaction time was 2 seconds (fluctuating between 1.2-3.1, never longer than 2.3 in the best endowed, nor than 3.1 in the poorest endowed, yet normal). Between the ages of 12-19 the average computed on 40 normals was 1.4 seconds, fluctuating between 1.2 and 1.8.

Thus R. concludes that *between the ages of* 6 *and* 12 *one may assume the average of* 3.2 *seconds* [in those from 12-19, 1.8, at most 2 seconds] *the lower boundary line of normality for immediate recall.* For 24 hours' *deferred recall* the average time for the same ages was 2.6 for the best endowed and 3.3 for the poorest endowed, yet normal. At the age of 12-19, 3.4 was the poorest average. *Averages, therefore, greater than* 3.5 *seconds argued with great probability*—in the ages from 6 to 19—*against intellectual normality and for pathological inhibition or deficiency.*†

Here, then, this test proves of considerable value —seeing that we have so few of this type—in being *defect-diagnostic,* or vice versa, in cases where there is difficulty in drawing the mark between normality at its lower boundary line and moronity at its upper level. It is true that the number of children tested is small and that these are foreigners as well (children of Budapest); however, Ranschburg being one of our foremost authorities on memory and a most careful worker, his results may be at least tentatively considered.

Test (d)—repeating of sentences: This test is one for immediate recall, *i.e.* the infixing of a number of syllables for momentary retention. Like test (a) it measures the memory-span, only the memory-span for sentences is much greater. In fact, the memory-span differs for different elements; it is smallest for senseless words, then follow unconnected meaningful words, then digits, and finally connected meaningful words (sentences)[13].‡

Binet originally asked for the repetition of a sentence of 6 syllables at *three* years of age, 16 at *six,* and 26 at *twelve.* In 1911 the three-year test was retained, but that at *six* and *twelve* omitted, 10 syllables now being demanded at *five* and 26 at *fifteen.* Only one reading was permitted and one entirely correct sentence out of two, verbatim without error, was required to pass. Terman's revision altered the procedure somewhat. He asks for 6-7 syllables at *three* (almost a third of 19 such children were able to repeat 10 syllables), 12-13 at *four,* 16-18 at *six* (one correct out of three or two with one error each), 20-22 at *ten,* and 28 syllables for adults. Bobertag found that most, but not all, *five*-year-olds passed the ten-syllables test, while the 26 syllables test proved too easy at *twelve.* If the sentences were simple, most *ten*-year-olds could pass. For older children he hardly finds such sentences suitable. Better a series of sentences of the same length but graded as to difficulty. Meumann asks for 8-10 syllables at *five,* 14-26 or 28 at *six,* 16-28 at *seven* and *eight,* between 14-30 at *nine,* and up to 40 at *ten!* Goddard retains Binet's *three* and *five* year test, but asks 26 syllables at *twelve.**

How account for these differences in opinion and how *intelligence diagnostic* can such an uncertain test be? To answer this we must first examine it closer.

There is a great similarity between the digits test and that for senseless syllables or words. They measure the *attention-span* and little else. The test for words with meaning brings in another element. These words are not automatically repeated —they are first *comprehended,* that is, *associated,* in the infixing. Hence, more difficult words are grasped less quickly or not at all.†

Comparing sensible but unrelated words with related words (*i.e.* sentences) one finds that the latter are far more easily retained than the former. In fact, Binet and Henri[14]‡ found that in children memory for the latter was possibly 25 per cent. greater than for the former.¶ These series of related words, these sentences, are grasped as such, are associated and comprehended ("apperceived") in the infixing, before they are repeated, and the rapidity, clearness, etc., with which they are grasped and retained depends upon their *sense* and their *special appeal* to the child's personal interest. The same sentence will appeal differently to different children, because no two are constellated alike. Or again, two different sets of sentences, unless quite colorless in interest, would give dif-

*It will be remembered that slowness of reply was also considered an unfavorable sign by Binet. On the other hand, it has been pointed out several times that some children are "slow and thorough," and take their time in order to be sure. (See Meumann, Arch. f.d. ges. Psych. Bd ix, 1907, also Zeit. f. Pädag. Psych., etc.; 13, Heft 3, p. 162, also his Vorlesungen, Vol. 1, p. 517). L. Scholz also comments in this sense. Anomale Kinder, Berlin, 1912, p. 108 (p. 70 in edition 1919.)

†Averages better than 1.8 are with great probability proof against the pathological nature of the poor endowment, as no such averages occurred in the abnormals between the ages of 7 to 16.

‡Comparing the memory span for series of real objects, numbers, sounds, and words, it is found that memory for objects (or pictures of objects) is superior to that for words, both in immediate and delayed recall. Kirkpatrick and Calkins found that seven times as many objects as words were reproduced in delayed recall. After memory span for objects comes that for auditory numbers, then sounds, tactual terms, verbal terms, auditory terms, emotional terms, foreign terms. (See 9, p. 553-554.)

*In the Hamburg studies alluded to below (the testing of a thousand ten-year-olds), a number of children were found who gave a correct verbatim repetition of *all* three sentences, of 37, 48, and 52 syllables.

†Abstract words, especially, with greater difficulty than concrete—and in the early ages not at all.

‡These authors found that in giving 7 unrelated words acoustically, the average retention at the ages of 8-9 for immediate recall was 4.6 words (at 12-13, 4.9 words). Meumann,[15] trying the same experiment, got lower results. At 8 the average was but 4 words; at 13-14 the average was 5.6. Meumann points out that the *extremes* also give us interesting data: thus he found "a great number" of children at 7 who were unable to get beyond 3 words with meaning, or 2 senseless syllables; among the 14-year-olds "a great many" who could repeat 8 words. Elsewhere Meumann[16] says: "Individual differences in aptitude for immediate retention are very great, both in children and adults. Bright children retain twice as much as dull children of the same age."

¶In adults, Ebbinghaus found that sensible connected series could be retained 9 to 10 times better than senseless series. (See article on Memory[3].)

ferent norms, even if applied to the same child. In these facts one may find some explanation of the variations in the results of the above experimenters.*

Two distinct elements are therefore noted in this test—the element of the *attention span* and the element of *grasp or comprehension.* Are they to be evaluated in combination or separately? And how do they each correlate with intelligence? of this presently.

As to the correlation between the sentence test as ordinarily employed (*i.e.* as a test for immediate recall) and intelligence, if one judge by immediate recall in general, one might say, considering the experiments of Winteler, Winch, Watkins, and the report of Parison (all of which are cited in Meumann,[15] p. 470, et seq.), together with the conclusions of Meumann,[16] that, *on an average,* good memory of this type and good class-standing go together; *i.e.* there is real correlation between good memory and good intelligence, though such correlation *need* not occur, for there are important exceptions.

And indeed these exceptions are noteworthy and lend interpretation to the test, for, though Parison and Watkins found conditions *on an average* as stated above, both had cases in which the poorly endowed (intelligence gauged by class standing) showed up good recall, and vice versa, while in Winteler's try-out no distinct superiority was evinced of the intelligent children over the unintelligent. Finally, it so happens that in Winch's experiments the very best student of all had a poor immediate memory.

In still another work, possibly the most thorough as yet undertaken of the sentence test,[18] the authors found one of the poorest students with a high memorial ability (testing with sentences) and one of the very best students with a decidedly meager ability, and they, too, assume that "after all in the errorless repetition of sentences, the matter of attention seems to play the chief role." To this painstaking study we shall return; here, however, let us say, that judging from the foregoing, we must pronounce the sentence test as given in the usual (Binet's) manner, neither *intelligence diagnostic* if well passed, nor *defect diagnostic* if badly done, for your normal or even exceptionally bright child *may* have a poor immediate memory, while the child making a splendid showing with such tests *may* be but meagerly endowed. Or, again, one may say that *attention* is the bigger element of this test, that is, the attention *span,* and such attention span in the child does not necessarily correlate with intelligence, but rather with age.

As to the number of syllables expected to be reproduceable in the normal child, we have seen that we cannot be over exacting and that but approximate figures can be given. Looking over the data studied, the following requirements seem approachingly fair: Sentences of 6 to 7 syllables at *three,* of 10 to 13 syllables at *four* and *five,* of 14 to 18 syllables at *six,* of 16 to 18 or 20 syllables at *seven,* of 20 to 25 syllables at *ten,* of 26 or more at *twelve,* of 28 or more at *fifteen* and over.

Before giving the sentences themselves which may be employed, we must study this test from still another angle: What if one offers the child a sentence *too long* for its memory span? On the one hand the child may get panicky and fail outright. Meumann has especially commented on this, saying "The presentation of too many letters or words may confuse the pupil and give rise to inhibition of attention, which in turn brings about a complete forgetting of the presented data. Hence it frequently happened that pupils who retained the complete list of seven words were able to reproduce only one or two when the list was increased to eight. In such cases the attention follows the presentation only up to a certain point; then the observer suddenly becomes aware of the fact that he is unable to follow so many words. And the consciousness of this fact immediately has a debilitating effect upon his retention and even drives out the words which he has already imprinted upon his memory. This is a phenomenon which has frequently been referred to as retroactive inhibition".*

To avoid this, it is wise to begin with shorter sentences and gradually increase the length. In the nervous or psychopathic child in whom the attention may hold with difficulty,* as well as in the feebleminded of higher grade in whom attention is of poor stability, this fact must especially be borne in mind. (Cf. also on test of learning.)

In the matter of *sentences,* however, the likelihood of such inhibition is not as great as in words or letters, for here one has a tendency to merely hold the *thought,* the "thread," of the whole, if the sentence becomes too long, and to repeat this thought in the recall even though the exact form is forgotten. Here, indeed, we come upon a factor in the evaluation of the sentence-repeating test which has interest and importance of its own. In apprehending a sentence one sizes up its elements, orders these, notes their relations and grasps the underlying connection which binds these into a unit. There is here an association play and an infixing of the thought, *the context,* not the verbatim lines. The richer the associations the stronger, more rapid and more durable the infixing.* This very process would have the natural tendency to deter a verbatim recounting of lines, would have the tendency to *disturb* the attempt. Hence one would get errors if word for word exactness were expected. This, of course, would not be the case when the sentences were simple and well within the attention span, but rather when such sentences became long enough to exert strain on this span.

In other words, even in normal intelligent individuals errors *may* occur within the attention span without being diagnostic in a negative sense (and

*There are still other factors which may play a great part in sentence retention, namely, rhythm, assonance, alliteration, clause structure, and secondary associations—for these have considerable influence on the infixing process. Thus a series of syllables in trochaic rhythm is more easily learned than one in iambics." And as for rhyme, it aids memory to such an extent that some 24 to 36 additional syllables had to be added in Meumann's experiment[18] to make the lines comparable in difficulty to unrhymed lines. (l.c. p. 453).

*And the more decided the tendency to infix the thought rather than the words. Thus the more intelligent the individual the greater this tendency. This may be the explanation of the fact that scattering in this test is greater in the better endowed than the less endowed."

we have already said that an especially good showing need not be intelligence diagnostic), and invariably *do, must,* in fact, occur if the sentence becomes long enough.

These errors have received especial consideration in the work of Gassmann and Schmidt, already alluded to. These authors divide the errors found into two types, sensible and senseless. The intelligent individual seeing he has lost grasp of some link or detail of the whole, nevertheless *hangs on to the sense*—or rather gets the sense if not the words,—and even if some element of the thought is missed, "fills in" adequately, in replying, and keeps control of his words so that no nonsense occurs. Despite the divergence from the exact original therefore, the repeated matter shows no gaps, no iteration, no senseless substitutions or words sounding somewhat similar to what was heard, yet not correctly grasped. This very *control* is found to be distinctly *intelligence diagnostic* as it disappears as one goes down the scale, and is found feeble or wanting in the very meagrely endowed or defective. For these latter the sound elements of lines are focused on rather than the thought content.

Of course, even the intelligent child may at times be "stuck" or lose the thread of thought through shifted attention, or be guilty of senseless errors. And vice versa, the poorly endowed may here and there make sensible errors (substitutes). It is only on the aggregate results that Gassmann and Schmidt compute their findings. It is found that the intelligent child has sensible errors in preponderance, the unintelligent senseless errors.

Where sensible errors occur one finds either synonyms substituted, or nonsynonyms which fit into the sense. In the instance of nonsynonyms some element of the sentence was not sharply or not at all caught, and so a substitute consciously or unconsciously interpolated.

Comparing the results of this estimation of errors with class standing,* these authors found the correlation to be very high, namely +0.87, and conclude this method of examination a veritable gauge of the intelligence endowment—and of possessing decided diagnostic value—that is, being "highly symptomatic" (to change Stern's phrase,† somewhat) of good intelligence.‡

Without question it is the element of comprehension and combination in this test which gives it such high value; but it is neither a comprehension test as such nor one of combinational ability, but a memory test *per se,* this interpolation and filling in of memory gaps being a normal *memory phenomenon* (Cf. No. 3).

The method I have used in giving this test is as follows: One first ascertains the *approximate* attention span as Binet does—but see our norms—(and notes the number of syllables correctly repeated). At least, three sentences should be given, two of these to be correctly reproduced and without error. When there is doubt as to the accuracy of the reproduction, give two more sentences and reckon on the basis of three out of five. Then, in order to provoke errors, one gives sentences approximately one-half again as long as the span just noted. With the printed or typewritten* test-sentences before you, one can easily check off the words correctly recalled, make dashes for omissions and jot down the actual changes from the text. One may then underscore the sensible errors with one line, the senseless with two (or use red and blue pencil or special marks, *i.e.,* line, circle, etc., as G. and S. suggest). If one wishes, one may differentiate the sensible and senseless minor changes from the sensible and senseless interpolations and study these separately. *The final computation, however, is done on the summation of sensible and senseless changes of whatever type they may be, and the results noted in percentage, i.e., percentage of senseless errors reckoned on the basis of all the errors combined, sensible and senseless. Everything correctly repeated is ignored.*† ‡

The children were previously given instructions as to how the test would be given, and also told to write each sentence as well as they had remembered it. "If you haven't remembered it quite exactly, it doesn't matter if you get it a little different."

Instead of marking on individual errors (this proved too laborious in so extensive an examination), the scoring was done on *the sentence as a whole,* sensible or senseless, and when the sentences were not completed the part that had been written was examined as to its probability of proving sensible or senseless if it had been completed. Each sentence was scored with 1, 2, 3, 4, or 5, *i.e.* very good, good, sufficient, wanting, failure—and the three averaged.

As to the sentences to employ, we are still on unsettled ground. Below I give the better of the sentences of Binet, Terman and Bobertag, with additions of our own. These sentences are not ideal, however, for they vary in structure, rhythm, difficulty, interest, and especially in the number of ideas contained. Gassmann and Schmidt, in order to attain uniform results, and test similarly and fairly at each age, offer a series in groups, in each

*Comparing the first (best) student of each class of the seven class-years (grades), then the second (next best) student, etc., *l. c.* p. 55.

†W. Stern (Differential Psychology) speaks of such test as having *wide symptomatic* value (*breiten Symptomwert*).

‡In contradistinction to the sentence-span ability *as obtained with the Binet method.* Thus in the case of the two students pointed out by G. & S., in whom one, among the poorest of his class, passed a good sentence repetition test, thus showing a good grasp-span, *i.e.* an excellent attention span, the other among the best of his class, showing a decidedly poor span, the test as given by computation of errors gave the proper correlation with the class standing.

In a publication just received out of the Psychological Laboratory of Hamburg (now part of the new Hamburg University) this test is found among eight selected as tests of especial endowment—and as such employed in the examination of a thousand ten-year-old children. It is pronounced an exceptionally good test, correlating "surprisingly high with intelligence as rated by the teacher." (Die Auslese befähigter Volksschüler in Hamburg. R. Peter un W. Stern. Beihete z. Zeit. f. angew. psychologie, No. 18, 1919. (See p. 144.)

*Copies of sheets of these sentence series may easily be mimeographed from a typewritten original.

†These latter are the directions of Gassmann and Schmidt, p. 53. (These authors also suggest that one may estimate the attention span, *i.e.* comprehension-grasp-span, by noting at which point the first error occurs.)

‡In the Hamburg studies just mentioned a simpler method is used: Three sentences of 37, 52 and 48 syllables, respectively, are written on the board—one at a time. The children look at the sentence for 15 seconds; then the word is given to "read," and the entire class reads the sentence aloud. The sentence is erased and the command given, "Write." Two minutes is allowed for the transcription (though this proved insufficient time).

of which four types of sentences are represented, all having the same number of syllables, and three sentences given under each type. Thus A: 3 non-rhythmic, B: 3 rhythmic (iambic and trochaic), C: 3 in which there is a chief and accessory clause, and finally D: 3 compound sentences. For an example of each, the following may serve:

A: When the explosion occurred, I trembled.
B. It's the early bird that gathers the worm.
C. The clock about which I told you has come.
D: School is over, and we are glad of it.

The text of the Gassmann and Schmidt sentences is for the most part not suitable for our children. However, even if this were not the case, it would be quite impossible to translate the sentences (ranging from 8 to 38 syllables, 12 sentences to each set!) and make them tally in English. It would nevertheless be interesting to try out a similar English series and learn if different results are obtained with these four various types. The sentences which seem best to these authors are those under C and D, and I have tried for the most part to use like sentences in the following list. An attempt is also made in our series to have, not colorless sentences, but such as will decidedly hold the attention:

6-7 Syllables.

I am cold and hungry.—6. (B.)*
I have a little dog.—6. (T.)
My brother went away.—6. (Bo.)
I am a good little child.—7. (Bo.)
Let us all go for a walk.—7.
Have you read the lovely book?—7.

8-10 Syllables.

We have not finished our lessons.—8. (Bo.)
Have you seen the cat on the fence?—8.
Were you ever in the country?—8.
I am going to my uncle to-day.—10. (Bo.)
Summer is over; soon school will begin.—10.
My father is coming home on Sunday.—10.
It is night and all the world rests in sleep.—10. (Y.)

12-14 Syllables.

When the train passes, you will hear the whistle blow.—12. (T.)

We are going to have a good time in the country.—13. (T.)

On a cold, clear night the stars twinkle in the sky.—12.

I hope I get a sled for my Christmas present.—12.

Let us all go for a very long walk this afternoon.—14. (Bo.)

After you have finished your lessons, you may go and play.—14. (Bo.)

The engine that pulled our train went by electricity.—14.

16-18 Syllables.

Very soon great air ships will be traveling across the ocean.—16.

I saw a beautiful doll that could walk and also close her eyes.—16.

They forgot to bring the funny page with our newspaper to-day.—16.

Walter had a fine time on his vacation. He went fishing every day.—18. (T.)

After the rain the sun came out, and with it a most beautiful rainbow.—18.

I never fail to go to the circus every year when it comes to town.—18.

20-25 Syllables.

The apple tree makes a cool, pleasant shade on the ground, where the children are playing.—20. (T.)

They say that winter will come early this year, for the birds are already flying south.—21.

Yesterday evening I met an old acquaintance on the street, whom I have not seen for years.—22. (Bo.)

Though the storm was raging, the life savers launched their boat, and brought the shipwrecked men safe to shore.—22.

One can now go West either by rail overland, or by water, using the Panama Canal.—24.

The awful storm blew the ship out of her course and forced her on a rock, where she was battered to pieces.—25.

26-28 Syllables.

The soldiers marched down the avenue wearing their helmets and with bayonets glistening in the sunlight.—26.

One meets bears on the road in Yellowstone Park, but the animals do not harm you, if one lets them alone.—26.

I saw the smith bend a piece of red-hot iron into a horseshoe and then adjust it to the hoof of a horse.—28.

They call him the human fly, because he climbs the face of a building without any aid save his hands and feet.—27.

On the way in from the country we had to change cars, and by getting into the wrong one, were almost left behind.—28.

The runaway horse was caught by a man who followed in an auto, leaned out and grabbed the animal by its bit.—28.

30-40 Syllables.

It was a glorious feat to cross from one continent to the other in an airship, and do so without a mishap.—30.

All went well at camp while the sun shone; but when the rainy weather set in the boys became discontented and wished themselves back home.—34.

The knights of old were strong and brave; yet the things they did were often so strange and wonderful that it is difficult to believe them true.—35.

The general asked for an interview with the opposing commander; and so it was arranged that the meeting take place in the open space between the two armies.—40.

I like winter best, for there is sleighing and everything looks beautiful covered with snow; while in summer, though the flowers bloom, it is much too hot to be happy.—40.

The farmers' life is made easier now through modern implements, and the farm itself is brought nearer the town through the automobile, which most farmers can afford.—40.

(*To be concluded.*)

*Those marked (B.) are Binet's, (T.) Terman's, (Y.) Yerkes', (Bo.) Bobertag's. In translating from the last, some slight changes have here and there been made.

THE RELATION OF ARTERIAL HYPERTENSION TO NEPHROPATHIES.*

By M. A. MORTENSEN, M.D.,
BATTLE CREEK, MICH.

THE subject of arterial hypertension has attracted the attention of the physician as well as the laity ever since correct methods of measuring it have been in vogue. The laity have no doubt stimulated our research along this line by becoming more or less familiar with the subject from the standpoint of prognosis, so much so that practically every physician has been forced to equip himself with proper instruments for taking blood pressure.

In the early study of blood pressure, the systolic claimed the greater attention, and perhaps does so at the present moment, but during the last few years, the diastolic pressure has been diligently studied, and I believe in the course of time will claim the major attention, so far as blood pressure is concerned. Every one realizes that there are marked fluctuations in systolic pressure readings, even at short intervals, ranging from 10 to 40 millimeters or more. The causes for this are many, and

*Read at meeting of Mississippi Valley Medical Association, Louisville, Ky., October 22-24, 1919.

they are, as a rule, beyond the control of the observer. Such factors as mental apprehension, worry, emotional disturbances, and nervous tension, may produce decided changes, and to this may be added temperature changes, previous exercise with stimulating or fatiguing result, lack of sleep, etc.

Marked fluctuations rarely occur in the diastolic pressure, the range being from 0 to 15 millimeters, rarely more than 10. For a number of years it has been my opportunity to observe many cases of arterial hypertension, and I have been more and more impressed with the great fluctuations in the systolic pressure and the comparative stability of the diastolic pressure under varying circumstances. Of late I am more interested in the reading of the diastolic pressure than the systolic, regardless of the astonishingly high readings sometimes found. At the time of writing this, I have two cases under my care that will illustrate this point. One has a blood pressure of 250 systolic, 90 diastolic, and in spite of the high systolic pressure enjoys moderate physical activity and has no urinary findings or subjective symptoms except intermittent claudication. The other patient has a blood pressure of 250 systolic, 160 diastolic, and is on the verge of coma, suffering with headaches, partial loss of vision, nausea, etc., and the urine contains albumin and casts. The first case has only a very slight increase of the nitrogenous waste in the blood, while the second has more than 100 per cent. increase. In observing this type of cases, the diastolic pressure is a far better indicator of the cardiorenal status than the systolic pressure, and in this study I shall endeavor to show the value of the diastolic readings in relation to the nephropathies.

Every one is familiar with the technic of taking blood pressures, so far as the systolic is concerned, and there is little chance of a misunderstanding, but in regard to the diastolic readings every one is not so positive. The true diastolic is at the end of the so-called fourth phase when the distinct click changes to a dull sound. Many observers read the diastolic when the sound of a pulse beat disappears, which is usually from 4 to 10 millimeters below the true diastolic. The readings to which I shall refer in this study are based on the disappearance of the sound, so are actually a few millimeters lower than the true diastolic.

The most common question asked the physician is, "What is the normal pressure for different ages"?, and the figures most frequently quoted are 120 systolic, 80 diastolic. This, I believe, is a reasonable standard which may vary as much as 10 per cent. and still be considered practically normal. Arthur Hunter and Dr. O. H. Rogers of the New York Life report an analysis of 62,000 systolic pressures in men and 5,000 in women during the years 1915-1916, in residents of the United States and Canada, with the following results:

Age.	Men.	Women.	Age.	Men.	Women.
15–19.....	120	117	40–44.....	127	125
20–24.....	122	118	45–49.....	129	128
25–29.....	123	119	50–54.....	133	132
30–34.....	124	121	55–59.....	134	134
35–39.....	125	123			

These figures are from fairly healthy individuals, and when one considers the range of years to be from 15 to 59, it is surprising that the increase is so small. The prevailing statement that one's blood pressure should be 100 plus one's age is not borne out in these figures, but would justify us in modifying the statement that the pressure should be 100 plus one-half the age. The systolic pressure in children from 3 to 15 ranges from 80 to 109 according to Judson and Nicholson (*Am. Jl. Dis. of Children*, Oct., 1914).

Personally I am convinced that a systolic pressure persisting above 140 and a diastolic above 90 is evidence of some changes taking place in the vascular and renal systems, and the earlier such individuals are instructed in rational care of the body, emphasizing the importance of eradicating focal infections and improving general elimination, the better the prospects of such an individual. In arterial hypertension there are three possibilities that must be considered, viz., cardiac failure, renal disease, and apoplexy, one or more of which is almost certain to appear sooner or later, and it is the physician's business to help avoid such possibilities.

To me it has been surprising to find how many cases of arterial hypertension develop a nephropathy, and my experience has convinced me that this is least amenable to treatment if allowed to reach an advanced stage. Some observations would rather indicate that only a small percentage of cases of true arteriosclerosis, so-called, have an arterial hypertension. Keigi-Saweda studied 204 cases of uncomplicated arteriosclerosis and only 12 per cent. of them had hypertension. He also reports that whenever a tension above 150 was found, nephritis must always be considered.

Pathologists state that arterial changes may be localized, or, at least, vary in intensity. Ostrander of the Kalamazoo State Hospital recently informed me that they frequently found advanced sclerosis of the vessels of the brain while other parts of the arterial system showed little or no change. The same condition, no doubt, frequently accounts for angina pectoris, with a localization of the sclerosis in the coronaries and beginning aorta without arterial hypertension or other subjective evidence of arterial degeneration. These things being true, it is reasonable to assume that in many cases localized arterial degeneration may take place in the kidneys, and in others, a general degeneration occurs, involving the capillaries and smaller vessels, including those in the kidneys, and this, I believe, is most apt to be true when we have a high diastolic pressure.

We all recognize arterial hypertension as a positive factor in clinical medicine, and the cause of this condition still remains an unsettled question. Some ask if it is the result of arterial degeneration or productive of the degeneration. Most authorities ascribe hypertension to a chronic toxemia, and we all recognize the causes for this may be many. Infections of all kinds may have a bearing, according to the case, and my impression is that they may be a source of injury to the tissues, whether they be acute or chronic. In addition to this must be considered what we may term the indulgences, such as excessive use of food, tobacco, alcohol, tea, coffee, etc., which of themselves cannot be definitely blamed for hypertension, but they serve to add an extra burden to the detoxicating functions of the body, if

we may call them such. This function is further inhibited by the defective activity of the normal channels of elimination. Sedentary habits, in combination with the above, form the maximum insult to the body welfare and are much in evidence in a large percentage of individuals suffering with arterial hypertension.

Huchard holds that excesses and, above all, errors in alimentation throw toxic substances into the blood, which produce a state of spasm of the arterial system, bringing on arterial hypertension and arteriosclerosis. Broadbent is of the opinion that "nitrogenous waste, and the products of imperfect metabolism," when present in the blood, raise the blood pressure. Russell contends that certain substances present in the blood, even in small quantities, cause arterial and capillary contraction, and this will be found to be the first stage of increased pressure, gradually progressing to arterial degeneration. The above idea is well illustrated by the action of adrenalin, ergot, and pituitary extract, which we know act by their presence in the blood, each in a little different way, on the wall of the blood vessel. With these facts in view, it is not a far-fetched idea that the nitrogenous waste products and other substances, the result of imperfect metabolism, have a detrimental effect on the tissues of the capillaries and arteries.

This philosophy concerning arterial hypertension led me to investigate the nitrogenous waste products in the blood of a large number of patients. We made a routine estimation of the nonprotein nitrogen in the blood of patients regardless of their condition. In cases having arterial hypertension with or without evidence of other complications, a more complete chemical analysis of the blood was made, which included nonprotein nitrogen, uric acid, and urea nitrogen. In addition to this, one series was studied by means of the renal efficiency diet test, and in each of these cases chemical analysis of the blood was made.

It must be remembered that arterial hypertension, as a disease, progresses insidiously and may be present for a long time before any subjective symptoms develop. In many cases the condition is discovered by accident, and it is with difficulty at times that one can make the patient believe there is anything wrong with his health. In arterial hypertension it is often difficult to find any other definite evidence of pathology. I believe that a careful study of these cases would justify us in concluding that in cases of arterial hypertension with a high diastolic pressure, we have the most unfavorable prognosis, while those with a low diastolic, regardless of the systolic, and no other pathology, have a more favorable outlook.

In the study of groups of cases presented in the accompanying tables, all stages of arterial hypertension are included.

In exhibit "A," 576 cases are represented in which the maximum blood pressure is 140 systolic, 90 diastolic, and in which the nonprotein nitrogen average is 31.0 mg. per cent., figures that coincide with the normal of other observers. The number of cases studied is large enough to lend value to the average, and the blood pressure limits are within the range generally considered normal.

In exhibit "B," data are presented in a series of cases in which chemical analysis of the blood was made because of arterial hypertension, particularly high diastolic; also a small group in which the diagnosis of nephritis was justified regardless of the pressure, and a third group in which a suspicious history, such as temporary presence of albumin or casts, or other symptoms caused apprehension regarding the condition of the kidneys. In the first group on this chart are included a number of cases on the verge of uremic coma and cardiac failure, and this explains the large amount of nitrogenous waste products in the blood. The average is also given on those with and without albumin and shows a considerable difference.

Table A.—Nonprotein Nitrogen in Blood in Diastolic Pressure Below 90.

Number of Cases.	Average Age.	Average Systolic Blood Pressure.	Average Diastolic Blood Pressure.	Nonprotein Nitrogen, m.g. Per Cent in Blood.	Range Nonprotein Nitrogen, m.g. Per Cent.
576	43	115	0.76	31.0	24–42

In exhibit "C," is presented a series where the renal efficiency diet test and chemical analysis of the blood were made, with grouping the same as in exhibit "B." In the first group of this series are none of the advanced cases as compared to the first group in exhibit "B," because all were able to take the diet prescribed for the test, a thing that would have been impossible in some of the cases in group "B."

Attention is called to the low range of specific gravity, increased quantity of night urine, retention of urinary nitrogen as well as increase in the nitrogenous waste products of the blood, which point to a renal inefficiency or nephropathy in varying degrees. In nearly half of those in group one, of exhibits "B" and "C," the ordinary urine examination would fail to reveal a pathological urine, and in considerable more than half of them would this be true, because some of these cases of arterial hypertension have only temporary traces of albumin, and because of this are frequently assured that the kidneys show no evidence of disease, thus instilling into them a false sense of security regarding their health.

Table B.—Nitrogenous Waste Products in Cases of High Diastolic Pressure.

	Number of Cases.	Average Age.	Range of Age.	Severe Infections.	Positive Wassermann.	Average Systolic Pressure.	Average Diastolic Pressure.	Average Sp. Gr. of Urine, 24 Hrs.	Albumin +.	Casts +.	Nonprotein Nitrogen, m.g. Per Cent.	Uric Acid.	Urea.
1. High systolic and diastolic pressure*	24	45	28–63	9	2	209	121	1.011	13	9	48.5	4.65	11.59
2. Low diastolic pressure, with nephritis	8	50	31–60	5	2	116	87	1.012	8	4	38.4	2.90	10.00
3. Low diastolic pressure, with suspicious history	28	43	23–60	16	0	127	94	1.014	0	3	34.9	2.70	8.09

*Average nonprotein nitrogen in cases with albumin, 55.4 m.g. per cent; without albumin, 42.2 m.g. per cent.

In group 2 of exhibits "B" and "C," the urine gives ample evidence of nephritis, and each one of these patients was aware of kidney disease, while

in group 3 trouble with the kidneys was feared because of temporary evidence. From the results of the renal efficiency diet test and blood findings, I fear that a nephropathy may be in process of formation in some of them without having produced sufficient absolute evidence to justify a diagnosis of nephritis.

In all such cases showing any abnormal evidence in the urine as studied by the renal efficiency diet test, the latter should be repeated at intervals of a year in order to be sure that the slow, progressive changes accompanying arterial hypertension are not in progress.

TABLE C.—RENAL EFFICIENCY DIET TEST AND CHEMICAL BLOOD ANALYSIS IN THE PATHOLOGICAL.

	Number of Cases.	Average Age.	Range of Age.	Severe Infections.	Positive Wassermann.	Average Systolic Blood Pressure.	Average Diastolic Pressure.	Average Ran. e, Sp. Gr. Urine.	Average Total Night Urine.	Albumin +.	Casts +.	Nitrogen Intake, Gms.	Urinary Nitrogen Retained.	Nonprotein Nitrogen, m.g. Per Cent	Uric Acid.	Urea Nitrogen.
1. High diastolic blood pressure*	36	49	31–70	21	0	206	121	8.8	758	19	28	13	4.2	41.0	4.3	12.3
2. Nephritis, with low diastolic pressure.....	11	67	25–59	7	0	158	83	7.0	750	11	9	13	4.5	41.1	4.5	13.7
3. Low diastolic, with suspicious history.....	22	46	29–63	14	0	136	79	10.0	621	0	4	13	3.7	38.7	3.1	11.1

*Average nonprotein nitrogen, 41.4 m.g. per cent in high diastolic with albumin.

In cases with an increase in diastolic pressure, similar precautions should be used so as to detect as early as possible any nephropathy that may be in process of development. Simple urine examinations, as ordinarily carried out, are insufficient to get all the evidence necessary to detect a nephropathy. If positive evidence can be found of the presence of a nephropathy, the earlier that precautions are taken to lessen the burden of the kidney, the better will be the prognosis, because when such conditions are well advanced anything that can be done has little or no effect.

SUMMARY.

1. The average ages in the groups presented indicate that arterial tension should be studied in all clinical cases over 40 years of age.

2. Both systolic and diastolic pressures should be studied, and when the diastolic is high, careful study of the renal efficiency should be made at yearly intervals.

3. High diastolic pressure is indicative of continual stress on the arterial system and more likely to produce renal inefficiency.

4. The renal efficiency diet test may show evidence of renal inefficiency, such as fixation of specific gravity, increase in night urine, and retention of urinary nitrogen, before positive changes in the blood pressure or positive increase in the nitrogenous wastes in the blood take place.

5. Persistent presence of albumin in the urine is not necessarily an evidence of marked renal inefficiency.

6. Observations on cases with low diastolic blood pressure justify a more favorable prognosis, regardless of the height of the systolic pressure, than a high diastolic.

A CLINICAL STUDY OF ECTOPIC PREGNANCY;

A NEW ETIOLOGICAL THEORY.

BY HERBERT E. STEIN, M.D.

NEW YORK.

ADJUTANT ASSISTANT GYNECOLOGIST, HARLEM HOSPITAL; ASSISTANT GYNECOLOGIST, NEW YORK POLYCLINIC.

THE following summary is based upon a study of forty-three cases occurring in the service of Dr. Haynes at Harlem Hospital. Out of a total of 580 gynecological operations, the ectopics thus constitute about 7 per cent.

In an endeavor to bring out the practical, salient features, I have eliminated as far as possible the irrelevant and theoretical considerations. In a study of this sort we ought to be in a position to confirm or invalidate certain conceptions appertaining to this most interesting but slightly understood pathological entity.

It is ordinarily believed that ectopic pregnancy occurs more frequently amongst multiparæ. Our series coincides exactly with this view. In fact, only six of the forty-three women had never been pregnant. Thirteen of the cases were primiparæ, twenty were multiparæ, one having been pregnant eleven times. Only six patients gave a history of previous miscarriage. This is rather interesting from the etiological standpoint, which will be considered later. Three patients had been operated upon for a former extrauterine pregnancy, one year, one and a half years, and two years ago, respectively.

A long period of sterility is looked upon as an antecedent to an ectopic pregnancy. This fact is not borne out by us. To be sure, one patient had been sterile thirteen years, and one eleven years, but the great majority had become impregnated within the last three years. Case No. 521 is of interest, the patient having had her last full-term child twelve years ago, seven miscarriages since then, the last one six months ago, and an ectopic pregnancy two years previous.

The ages ranged from 23 to 40, although most of the cases occur in women under 30 years of age.

When we come to consider the rôle infection plays, our best criterion is the condition *in vivo* of the other tube. It is well known that the gonococcus usually involves both tubes to a certain if not equal degree. Still in these forty-three cases a double salpingectomy was deemed necessary only nine times. Thus the other tube showed evidence of inflammatory involvement in about one-fourth of the cases. Many specimens were sectioned only at the site of the ectopic pregnancy so as to verify the diagnosis by the presence of chorionic villi. At this point, however, the muscularis and mucosa are so attenuated, either by rupture or the invasive and erosive action of the trophoblasts, that it is difficult to demonstrate round cell infiltration. But of those tubes that were sectioned throughout, only about one-third showed the presence of round cell infiltration and connective tissue replacement, due to chronic inflammatory changes. Furthermore, in the multiparæ the tubes could have been only slightly if at all diseased, to permit of frequent normal pregnancy. Indeed one patient became nor-

mally pregnant after a unilateral salpingectomy, indicating the patency of the remaining tube. Subsequently this tube became the site of an extrauterine pregnancy. Miscarriages are not infrequently associated with or followed by infection of a mild degree, which, travelling along the the lymphatics, produces peritubal inflammation with subsequent adhesions. But a very small percentage of cases had given a history of previous miscarriage. Thus we must admit that infection is only of minor importance from the etiological standpoint.

It has been the usual teaching, handed down from book to book, that the normal meeting-place of the ovum and spermatozoon is in the tube. There is no evidence in favor of this except the occasional occurrence of ectopic pregnancy. Nature as a rule does not work in a roundabout fashion. Why the two elementary cells, in every normal case, should first meet in the tube, then turning about, travel together toward and into the uterus, is rather difficult to conceive. It is my opinion that the normal meeting place of the ovum and spermatozoon is in the uterus. The male cell is universally attracted toward the female. Whenever and wherever union takes place, then and there cell multiplication, decidual reaction, and pregnancy supervene. The tube may be perfectly capable of accommodating both ovum and spermatozoon separately, but as cell multiplication immediately takes place, the resulting increased mass is too large to pass onward toward the uterus. The pregnancy thus continues within the tube until the inevitable termination. Various factors may account for the meeting taking place in tube: (1) Late ovulation, *i.e.* late in regard to insemination. The sperm cell may be well along in its ascent, while the ovum is just entering the tube. (2) Hypermotility of the spermatozoon. (3) Lodgement of the ovum in a recess or congenital ampulla of the tube. (4) Mild salpingitis causing stricture or interference with the ciliary motion or contractility of the musculature. The inflammation must of necessity be a mild one, as a moderate or severe involvement tends to close the fimbriated end very early, thus precluding the possibility of the ovum even entering the tube. Spermatozoic hypermotility or late ovulation could account for the few undoubtedly primary ovarian or even abdominal pregnancies.

The most vital element of this subject is undoubtedly its diagnosis, for upon the recognition of the presence of an ectopic pregnancy may depend the life of the patient. But probably no gynecological condition is so difficult to diagnose as extrauterine pregnancy. I beg to present the apparently startling fact that out of forty-three cases we correctly diagnosed only twenty-four, *i.e.* about 60 per cent.

Let us now consider why we fell down on 40 per cent. of the cases. A proper diagnosis of any subject depends upon a good history, physical examination, and laboratory data. Ordinarily physical examination is of prime importance and the other two means are but adjuvants in arriving at the proper conclusion. In ectopic pregnancy, however, we have learned to pay most attention to a good history. What then can be considered a typical history? A young woman who has gone ten days beyond her expected menstrual epoch is suddenly seized with severe intermittent cramp-like pains in her lower abdomen. These are preceded, associated, or followed by some vaginal bleeding. The cramps are repeated and accompanied by dizziness, weakness, or fainting spells. These latter symptoms are indicative of a slight hemorrhage into the wall of the tube or a moderate leakage of blood into the peritoneal cavity. They constitute the so-called diagnostic feature of the disease. If allowed to go unrecognized or not elicited by a good history, the bleeding continues until the patient presents all the signs and symptoms of shock due to internal hemorrhage, such as marked pallor, small thready rapid pulse, thirst, dyspnea, etc. Diagnosis then is no art but a reproach upon our ability.

Unfortunately, Nature has not reproduced two identical abnormal conditions any more than two normal ones. It is the deviation from the type that makes ectopic pregnancy so difficult to diagnose. For instance, the menstrual history had gone on uninterruptedly in twelve cases. Six patients had an irregular type for the past four to six months, and one for the last four years. The pain, usually quite characteristic, is misleading in those patients, who have had pelvic discomfort for a period long antedating the beginning of the ectopic. This misled us in four cases. The history of fainting spells we have often elicited after the operation, the busy house-surgeon not having had sufficient time to go into details, and the patient not considering fainting more than a daily occurrence.

Thirteen patients gave a history of vomiting during the few days previous to admission to the hospital. As this is usually due to toxic irritation of the peritoneum rather than to bloody extravasation, one is liable to misinterpret its significance. In all probability it is a concomitant of the shock. A few patients complained of frequent, burning urination, a very common symptom in infections of the genitourinary tract.

The blood picture has not been of great assistance, except in cases of frank hemorrhage. A moderate amount of bleeding gives an increased leucocytosis and a moderately high polynuclear count, thus being very similar to a pyogenic condition. Reduction in the hemoglobin and red glood cells is of course indicative of free bleeding.

When we come to the physical examination, we are again confronted by paradoxical data. For instance, why should a clean ectopic pregnancy, ruptured or unruptured, produce tenderness, rigidity, and even a rebound sign?—all signs expected in a toxic peritonitis, not in a clean simply irritating type. Still this state of affairs was present in twenty-two cases, fifteen having ruptured, with free blood in the peritoneal cavity; three were unruptured; two were old partial ruptures that had become encysted, and two were adherent to the appendix.

The vaginal examination, the *sine qua non* of gynecology, is only one link in the evidence, very often in fact misleading, when the history alone would be sufficient to make a diagnosis. The oft described sausage-shaped tumor of the tube we only rarely encountered. As the ectopic growth develops in one part of the tube, it tends to form a rounded rather than an elliptical mass. It is usually tender, not movable, and varies in size, accord-

ing to the degree of maturity of the ovum. In one case, the mass extended half way up toward the umbilicus. The tube itself does not assume such proportions, but the bowel and omentum becoming adherent to it, constitute the mass. Another case, an abdominal pregnancy, filled the entire pelvis and hypogastric region with an irregular hard tender enlargement. If a partial rupture or tubal abortion has taken place, with blood accumulation in the cul-de-sac or fornices, an indefinite boggy, crepitating sensation is obtained. It is difficult to describe but is absolutely characteristic of free blood in the peritoneal cavity. The cervix and uterus were softened and enlarged in only eleven of the cases, there being no appreciable change in the remainder.

The nineteen cases which we failed to recognize, were diagnosed as follows: eight pyosalpinx, three pelvic abscess, three fibroid uterus with cystic ovary, one cystic ovary with salpingitis, one fibroid with salpingitis, one broad ligament cyst, one retroversion with double pyosalpinx. I will just briefly cite a few of these cases:

Case 407.—Age, 23, married, no children, 4 miscarriages, menstruation every twenty-eight days for four days, last period being on time. During the past year she has suffered with pains in the lower abdomen, particularly after menstruation, vaginal discharge, and frequent micturition. Examination reveals tenderness, rigidity in both lower quadrants, and a rebound sign present. The cervix and uterus are slightly enlarged but otherwise normal. There is a slight induration in the right broad ligament. Leucocyte count 12,500, polynuclear 79 per cent, lymphocytes 21 per cent. Temperature 101°, pulse 90. Diagnosis pyosalpinx. Operation revealed a right tubal pregnancy aborting through the fimbria.

Case 567.—Age, 25, III-para, last two years ago, one miscarriage six years ago; operation for prolapsus uteri six years ago. Menstruation very irregular during past nine month, pain in lower abdomen during past four months, associated with mucopurulent vaginal discharge. During the past three days she has had a vulvovaginal abscess which ruptured on the day of admission to the hospital. Temperature, 99°; pulse, 80; respiration, 24. On the second day the temperature rose to 102°, pulse to 100, gradually becoming normal on the fifth day. The fundus is anterior and slightly enlarged, the cul-de-sac and right fornix are occupied by an indefinite mass. Examination three days later shows a large soft fluctuating mass filling the cul-de-sac, the adnexa not being palpable. The case was diagnosed one of pelvic abscess. Preliminary aspiration of the posterior cul-de-sac revealed three ounces of dark fluid blood. Another examination, immediately made, disclosed a small mass occupying the left adnexal region. The diagnosis of ectopic pregnancy now made was verified by laparotomy.

Case 207.—Age, 37, II-para, has had one miscarriage; menstruation irregular for the past six months, vaginal bleeding during the last six weeks. The main complaint was of pain in the left side of the abdomen and progressive weakness. On examination a mass was mapped out extending half way up toward the umbilicus and two inches to the right of the median line, filling the left iliac fossa. Vaginal examination showed the whole pelvis filled with an irregular, nodular mass. Leucocytes 12,000 polynuclears 80 per cent., lymphocytes 20 per cent. Diagnosis, fibroid uterus and cystic ovary. Operation showed an old adherent ectopic pregnancy with right pyosalpinx.

Operative intervention has been undertaken as soon as the diagnosis was established. In cases of rupture, we did not wait until the symptoms of shock subsided, but laparatomized the patient as quickly as possible. The offending tube was clamped off, as much of the blood clot was scooped out as possible, and layer closure of the abdominal wall was undertaken without drainage. The operative findings and procedures were quite varied. Curettage was undertaken six times, either for diagnostic purposes or under a false belief of intrauterine pregnancy. The uterus was found empty in five of the cases; in the other one it still contained considerable decidual tissue.

Twelve of the cases had not yet ruptured, eighteen cases had ruptured with copious intraperitoneal hemorrhage, and six revealed tubal abortion. It is most interesting and rather inexplicable to account for the remarkable distensibility of some tubes, one being the size of an adult's fist and still no rupture had taken place. Another tube, not enlarged much beyond the normal, had ruptured and caused excessive hemorrhage. Others were bound down by omentum and intestines at the impending site of rupture, and thus the hemorrhage was delayed. We encountered three old encysted ectopic pregnancies and one abdominal, both fetus and placenta having been implanted upon the bowel.

The associated lesions were as follows: Three pyosalpinx, two hemorrhagic cyst of the ovary, two adherent appendices, one fibroid, one retroversion. The following were the operative procedures: Thirty-two unilateral salpingectomies and nine bilateral salpingectomies were performed. The ovary in part or whole was always left in situ if at all possible. Posterior colpotomy was performed three times, twice for diagnosis, once for drainage. Hysterectomy and uterine fixation were each done once. Appendectomy was practised only eight times. In case of rupture with free blood in the peritoneal cavity, we omit appendectomy, as we fear that the blood makes too good a culture medium for the colon bacillus that might escape from the appendectomy stump.

The postoperative treatment is very simple—glucose, sodium bicarbonate, and whiskey are given by rectum every six hours for the first twenty-four hours. In four cases 500 c.c. saline infusion was administered, but no transfusion was given. Morphine is used if found necessary. The patient receives an enema and a mild catharsis respectively sixty and seventy-two hours after operation.

The prognosis is most excellent. Even those patients who have had a very copious hemorrhage respond and recuperate very promptly. Two patients of this series died, one five days after operation. During the first two days the latter showed all the signs and symptoms of an acute gastric dilatation. Under treatment this cleared up, but on the fourth day the temperature rose to 105°, she became cynotic, and died the following day. Unfortunately we could not obtain a post-mortem. The other patient died six days after operation. The post-mortem showed short chain streptococci in the peritoneal cavity.

From a study of the above series, I believe the following deductions are permissible:

Every patient who has missed her regular period should be examined for and suspected of ectopic pregnancy.

The condition occurs much more frequently among multiparæ.

Our knowledge of the etiology is very meagre, but antecedent infection is not so important as is ordinarily believed.

The proper diagnosis can be made in most cases; in some it would be obviously illogical, and in others it is apparently impossible.

Operative intervention should be undertaken as soon as the diagnosis is verified, whether the tube is ruptured or not.

41 West Seventy-fifth Street.

THE CAUSE, PREVENTION, AND CURE OF INFLUENZA AND ALLIED DISEASES.

By ALFRED KAHN, M.D.

NEW YORK.

We are now again in the midst of a serious influenza epidemic. Numbers of people have been confined to their homes and beds. Many lives have been sacrificed. Other victims will follow in order. The medical profession has again been challenged. The whole country is crying for a cure. Are we helpless? We are not. But our memories are short. For several years I have made certain clinical observations in the course of my practice. I have observed certain phenomena, which I do not think have been noted before. These phenomena have surely been seen by others, but I do not believe that they have been recorded. I make this statement off the palm, as it were. I did not intend presenting this paper to the profession in this form. I had intended waiting for further data. I had intended looking very thoroughly into the literature of the subject,—and lastly, I had intended writing a more detailed article sometime in the future, at my leisure. But as we are now in the midst of a serious epidemic, and as I believe that this knowledge may be of great value to the country, I am presenting it in this hurried form, without bibliography, without mentioning names of other worthy clinicians who would doubtless deserve recognition were it possible for me at this date to review the history and use of the drug and formulas here given. And with this in mind, may I ask indulgence on the part of the profession?

Now, I have an idea that we have laid too much stress upon the germ which causes influenza. Please bear in mind, as I proceed with this theory, that what I state here as regards influenza also holds good with regard to some of the other infectious diseases, and some other diseases perhaps not infectious,—hay fever, for example. I do not mean in the last analysis that the bacillus of Pfeiffer is not the causative factor of the disease, but what is of prime importance to each individual victim of the disease is the special soil in which the germ is planted. Of course, it is well known and it is often stated that before a germ can produce a disease, the soil upon which the germ is planted must be ripe or must be in a receptive mood for the reception of the germ. And this is important. But I contend that the soil upon which the germ is received, if you will, is even a more important factor in the causation of the disease than the germ itself.

Now, when we say the soil must be ripe for the reception of the germ, just what do we mean and why is it such an important factor? Let me make several clinical observations, simple in themselves, but like many simple things, full of meaning.

First Observation.—First, let us observe that mucus is secreted in the nose,—let us say that it is of a watery nature. It is admitted that this secretion has a salty taste. It is admitted, I am sure, that when a patient for example, has an acute rhinitis, the turbinates swell up and become congested, there is a hypersecretion from the nose, and this secretion has a salty taste. Now, you will answer if the question is put, that the secretions in the nose come from the cells of the mucous glands lining the mucous membranes of the nasal cavities. In the last analysis, the source of the excretions in the nose come from the food taken into the stomach. In the process of metabolism, food is taken in the stomach and intestines, absorbed into the bloodstream through lymphatics, etc., and carried to all the cells of the human body, and I contend, excreted not only from the kidneys in the form of urine and from the skin in the form of sweat, but also from the nose, throat, and lungs. If the food digested is highly irritating, it will irritate the kidney and bladder. If the food is highly irritating, it will irritate the skin, and you may have the various skin eruptions. If the excretions are highly irritating, you will have inflammation of the mucous membranes lining the nose (acute rhinitis), lining the throat and larynx (acute pharyngitis and laryngitis), lining the bronchi (acute bronchitis), and lining the lungs (pneumonia). So the gist of the subject is that, according to my view the mucous membranes lining these passages have the function of excreting just the same as the skin. They also have the function of absorption and so has the skin, but to a very much less degree. But the factor of absorption is not the cardinal point in this paper, so I will pass it by.

Second Observation.—If you agree with me, you admit, according to the first observation, that the nose is an excretory organ, or that it has an excretory function, and that these excretions, in the last analysis, come from the food ingested. My second observation is this, and almost any man doing nasal work has observed the phenomena: Very often upon inserting into the nose a probe or an applicator tipped with medication, there is a sudden gust of smoky vapor, which can be very favorably compared to the fumes of hydrochloric acid when exposed to the air. I have never been able to determine what this fume was but I am inclined to think that it was a fume of hydrochloric acid formed in the nasal chambers by the substance on the medicated applicator coming in contact with certain vapors in the nasal chambers. I am personally convinced that some chemical reaction takes place. Such a reaction is met with every now and then during the course of a nasal practice, and if my theory is correct, it will show that intense chemical reactions might conceivably take place at a shorter or longer interval in the nose. It will also tend to show a close relationship of the upper air passages, bronchi, trachea, and lungs to the food ingested, broken up through metabolism and excreted (the soil), on the one hand, and to the invading organism on the other. It will also promptly indicate where treatment

must be applied, and I will in a moment demonstrate that treatment applied at this point will prevent influenza, and if rightly applied, promptly applied, will, I believe, act as a specific to the diseases under consideration.

Third Observation.—This observation, I believe, will tend to clarify the other two, especially the last observation. Several years ago, Mr. W. H. Y., an old patient, who had been in my charge for several years and who was a yearly sufferer from hay fever, presented himself to me for treatment. He was suffering from an intense attack of hay fever. His eyes were watering, and if I may use the term, his nose was pouring out secretions. He would use up a handkerchief every few minutes. The turbinates of both nasal chambers were intensely engorged, the mucous membrane was in shreds and had the appearance as if a cautery had been applied to it. Leave Mr. Y. here for a moment. It is generally known that hay fever makes its appearance at certain seasons of the year, and it is generally believed that hay fever is caused through the agency of plant pollen, and I am willing to accept this. It is also admitted that certain individuals are subject to hay fever and that other individuals under the same conditions are not troubled at all. It is also well known that certain individuals present different reactions to different foods, that what may act as an irritant to one individual may not be an irritant to another, and that conversely what is sugar to one man may be poison to another.

It is also well known and admitted that poison ivy will act as an irritant to the skin of certain individuals and that on the skin of other individuals it has no effect whatever. Now, I contend that the eczema caused by poison ivy is due to an irritant produced between the perspiration or excretion of the skin on the one hand and some product or element in the poison ivy on the other; that there is a chemical reaction resulting in the formation possibly of an acid and that this acid produces the eczema. Now, there must be in these susceptible individuals some product of metabolism, excreted in their perspiration that is entirely absent in the perspiration of other individuals who are not susceptible to the poison. Now, I believe that the same state of affairs exists in hay fever. That there is something in the excretions from the nose which, when coming in contact with the pollen, produces a slow chemical reaction, with the formation of an acid (probably hydrochloric acid), and that this acid causes the inflammation in the nose; and I believe that the fumes spoken of in observation No. 2 are the fumes of hydrochloric acid, and that in a small way on the introduction of my applicator a small reaction took place with the formation of hydrochloric acid, but in an insufficient quantity to cause much irritation. And in passing I might add that such a condition may possibly have something to do with the production of catarrh of the nasal passages.

Observation 4.—It is well known to all oculists that certain foods—sugar, pies, cakes, strawberries, a heavy protein diet—may produce conjunctivitis, that often patients presenting themselves with acute conjunctivitis will get well when some error in diet is changed. Dermatologists will tell you the same thing. There are certain cases of discharging nose, due to the same factor. When the diet is changed, the disease clears up and the secretion stops.

At the beginning of this article I pointed out that in the last analysis all secretions, whether it be from the kidneys, from the skin, whether it be tears, secretions from the nose, throat, lungs, all of these secretions and excretions come from the food taken into the body. This is surely an axiomatic fact, and I feel certain that it is not necessary for me to reason this out with the reader. So, having this in mind, let me try to answer the question, why is it that when certain food is taken into the body and metabolized and excreted by some individuals, these excretions act as irritants, either alone (conjunctivitis, skin eruptions, certain nasal discharges) or act as irritants when brought in contact with some outside element, such as the pollen of plants (hay fever) poison ivy, certain bacteria. There seem to be only two answers, and one of these I think is hardly to be considered. I will discuss these two answers as we proceed. Let us take for argument's sake, two individuals exactly alike if you will, the one is susceptible to hay fever, poison ivy, influenza, or a hundred other diseases—the other conversely, not susceptible to any of these diseases. Let us agree for argument's sake that the susceptible individual is susceptible to these diseases and that his susceptibility is due to some peculiarity in his ingestion and metabolic processes. Now, let us say in these two individuals that, so far as we can see, their anatomical make-up is equally perfect, their stomach, bowels, kidneys, etc., are equally normal. And still one is susceptible and the other is not. The secretions from the stomach, liver, pancreas, and organs of digestion in each individual are equally perfect. Now, these facts being true, what other element could cause the difference? To my mind, the difference is due to bacterial life in the intestines. Their bacterial flora is different. I believe it is due to this difference of bacterial flora in the intestines that certain ferments are formed in some individuals and not in others. I believe that these ferments are absorbed in the processes of metabolism, and that when these ferments are eliminated through the kidneys, they may tend to irritate the kidneys (Bright's disease), through the skin (various skin lesions), through the nose (rhinitis), in the tears and glands of the conjunctiva (conjunctivitis). These secretions of fermentation in the intestines, when brought in contact with certain outside elements, the pollen (hay fever), the ivy plant (poison ivy), the bacillus of Pfeiffer (influenza),—this explains your ripe soil; this explains your receptive soil.

Now, if what I say is true, if you can stop the fermentation taking place in the intestines in these susceptible individuals, if you can do this, there will be no receptive soil in the nose, throat, lungs, etc.; if you have a drug that will do this, you have a drug which will act as a preventive and a curative agent—and we have such a drug

—and it is creosote; salol (phenylsalicylate) is excellent, but the master is creosote.

The other factor that would tend toward the elimination of irritants would be due to insufficiency on the part of some organ of metabolism —for example, an insufficiency of the liver might cause diabetes, and the history of diabetes is very often the history of the elimination of irritants. In addition diabetic patients are easy victims to infections. They present a peculiarly ripe soil to an invading organism. The same may be true of a diseased kidney. The kidney not functioning properly allows irritants to pass out through the emunctories, bringing the individual in the class of a ripe soil. This may be true as pertains to other organs, and in a similar way. But in a consideration of influenza I think this factor of an insufficient functioning organ is hardly to be considered, as most of the victims are in the prime of life and in perfect physical condition. Therefore, I believe the other view, fermentation in the intestines, is the etiological basis.

Creosote.—It is not necessary, in a paper of this type, to enter into a long dissertation on creosote. It has been used often with success by many clinicians. It has especially been praised in the treatment of tuberculosis and pneumonia. I do not know whether it has ever been recommended before by any other physician, especially for influenza. However, in any case, I am indebted to other men for nearly all of my information regarding this drug. The drug has been used in many ways, even before the time of Socrates. And I do not claim any priority in the matter. In the diseases discussed, I believe the views and theories here propounded are original, and in this respect I possibly am entitled to priority. I have not had time to look into the literature of the subject. An excellent formula for administering the drug is

℞ Creosote carbonate.....ʒss
Sapon medicat .....ʒi
Caps No. 60
Sig: 2 every 3 hours; 10 to 12 daily.

Another mixture is creosote carbonate administered in peppermint water with a small addition of glycerin, and an adult dose is 15 minims every 3 hours. For children it is well to give creosote carbonate according to the following dosage:

1	year	4	to 15	grains	daily	in 4	doses
2 to 4	"	15	to 45	"	"	"	"
4 to 6	"	45	to 60	"	"	"	"
6 to 10	"	60	to 75	"	"	"	"

The patient is apt to get much relief and comfort and an early breaking up of the tenacious cough by inhaling the following:

Beechwood creosote
Alcohol
Spirit of chloroform, aa equal parts

or the following inhalant:

Tincture of benzoin comp.....ʒi
Menthol .....gr. xxx
Beechwood creosote .....ʒii
Oil of gaultheria .....ʒi

This should be inhaled from a steaming kettle, using about half an ounce to half a pint of water. If there is much irritation of the nervous system, give creosote valerianate, 6 drops 3 times daily. after meals. If the influenza is of the rheumatic variety, give guaiacol valerianate, 6 drops 3 times daily after meals.

These are average doses, but my advice is to push the drug to the highest point compatible with any individual case. If the drug is carefully regulated, the stools should be practically odorless. Of course, one might smell the creosote, and if you can keep the stool odorless, I can almost surely state that your patient will recover. In a given case, everything else being equal, the odor of the stool after the administration of creosote is a valuable prognostic sign.

I do not mean in this that any given individual, for example one who is a sufferer from hay fever or who is inclined to be susceptible to poison ivy, will necessarily be subject to influenza; it has been my endeavor merely to point out that the body processes present a striking similarity. A patient may be an easy victim, for example, of hay fever or poison ivy or other diseases, but this would not necessarily indicate that he would be an easy receptive individual, a ripe-soiled individual, if you will, to influenza. I have endeavored to explain this very difficult subject and I hope I shall not be misunderstood. In conclusion, I repeat that it is my belief that if the suggestions here offered are carefully followed, many a patient will be cured and it will be a means of bringing the epidemic to an end. A good preventive or prophylactic prescription to give, one which I have been giving to my patients, and none of them have been taken down with the disease, is the following pill:

Creosote ¼ grain.
Ex. nux vomica, ⅛ grain.
Pepsin (1-3000) 1 grain.

I should advise the use of such a tablet 3 or 4 times every day, after meals. The patient must not skip a day.

50 East Forty-second Street.

THE PROSTITUTE IN JAIL:

AN OPPORTUNITY FOR PUBLIC HEALTH WORK THAT GIVES RESULTS.

By HERMAN GOODMAN, B.S., M.D.

NEW YORK.

FORMERLY VENEREAL DISEASE OFFICER, CAMP LAS CASAS, PORTO RICO.

THE vigorous efforts of the past two or three years for the abatement of the so-called venereal diseases have given most wonderful results as the returns of our army both here and abroad have shown. The United States has almost unanimously accepted one plan of action even now that the war is over, and during the period of active training the Federal Statutes governed a zone about each camp and cantonment. These statutes were of a stringent character, and prostitution and the business of prostitution were kept at a most inactive level.

In Porto Rico a camp was organized for the training of 12,000 men for the world conflict.

Former experience had taught that the possibilities for venereal disease infections among the drafted men from the interior coming in contact with the vice of the seaport towns would result in many infections. The Attorney General of Porto Rico, Mr. Howard L. Kern, made a most splendid effort to follow the plan laid down by the Federal authorities for the suppression of prostitution and the liquor traffic for the protection of the men in uniform.

The confinement of a large number of prostitutes through the activities of the Judges and District Attorneys of Porto Rico[1] made medical examinations possible. At the Hospital Jail of Ponce, 43 women among the 332 confined, or more than 12 per cent., had infectious syphilitic lesions. The lesions had all been neglected and none of the patients had had any treatment prior to admission. Of the lesions seen, we had: Chancres, 13; mucous patches, 2; condylomata lata, 19; skin syphilides, 8; congenital syphilis, 1.

The routine blood Wassermann test was done on all patients. The number of four plus Wassermann tests on women without lesions was 119. The percentage of women who were without lesions but had four plus Wassermann tests was 42. This indicates that this number at least were in the latent tertiary stage or the stage of potential active syphilis. The syphilitic index was 50 per cent., since 165 of the 332 women were positive clinically and serologically.

In the San Juan institution we found two cases of chancre; one case of syphilitic ulcers of the cervix; one case of incised and ulcerating inguinal adenitis; one case of secondary maculopapular syphilide; and ten cases of condylomata lata. On routine blood examination of all patients, we found 62 with four plus positive Wassermann reaction.

At Arecibo, the social diseases among the 332 women were especially prevalent. Twenty per cent. of the women had active infectious syphilitic lesions, and 70 per cent. gave four plus Wassermann reactions.

At the three jails, 12 per cent. of the women had dangerously infectious syphilis. Forty-two per cent. more on routine blood examination had four plus positive reactions. Since the Wassermann is effective in only 80 per cent. of latent tertiary syphilis, this indicates that eight per cent. more were in the latent stage, free of lesions, in whom one examination did not give the positive results. The true index of syphilitic infection among the women was, therefore, 62 per cent.

Comparative figures from Vedder[2] are very interesting:

Average figures are probably given by Kneeland, who says that the records of the Bedford Reformatory for girls show that 25.56 per cent. of the 647 inmates have clinical manifestations of venereal disease. With the Wassermann test, 224 or 48 per cent. have positive reactions, and 30 or 6.4 per cent. gave doubtful reactions. In a later statement, Davis says that 51 per cent. of the inmates of this reformatory are syphilitic. Walker in an examination of 337 prostitutes in Baltimore found that 57 per cent. gave a positive Wassermann reaction.

Sullivan and Spaulding find among 63 women arrested for alcoholism only, syphilis was found in 42.8 per cent., while 9.6 per cent. show a doubtful Wassermann. Among 94 women arrested for alcoholism and other offenses, syphilis was found in 46.8 per cent., with 14.9 per cent. more showing a doubtful Wassermann. Among 243 prostitutes syphilis was found in 65.5 per cent. with 9.5 per cent. more showing a doubtful Wassermann. Among the entire 500 consecutive cases, who were all regular and irregular prostitutes, 44.7 per cent. were undoubtedly syphilitic, while 9.5 per cent. more had a doubtful Wassermann.

By a special study[3] made to answer the question, "At what age is the prostitute most dangerous?", we determined that 139 of the 721 girls were under 17 years of age; 42 per cent. of this group had three or four plus Wassermann reactions. Fifteen per cent. of these young girls had active, infectious syphilitic manifestations, such as chancre, mucous patch, or condylomata lata.

The age period from 18 to 22 gave us 388 prostitutes or 48 per cent. of the total studied. Of these 388, 193 or about 50 per cent. were strongly Wassermann positive; and 11 per cent had active genital lesions of syphilis.

One hundred and forty-seven girls fell into the next age period, 23-27, of whom 45 per cent. were serologically positive, and 11 per cent had dangerous syphilitic manifestations.

Only 64 women were in the age group 28-32, and 43 per cent. of these had three or four plus Wassermann reactions but only four per cent. were with active lesions.

Beyond 32, the number of women became much smaller, and the percentage of positive Wasserman reactions became much lower, while none showed any active infectious manifestations of syphilis. Briefly stated:

33-37: 36 women, 38 per cent. Wassermann positive; 38-42: 12 women, 33 per cent. Wassermann positive; 42-56: 5 women, 20 per cent. Wassermann positive.

These old women were not engaged in the active prostitute life, as might readily be supposed, but were either maintaining houses of ill-repute, or acting as servants and lookouts for the younger girls.

In the series studied, we had 422 whites, 304 mulattos, and 65 negresses. Even with such disparity in numbers, the percentage of Wassermann positive cases was constant, about 47 for each color.

In the ratio of active syphilitic lesions, however, there was a marked difference. The whites gave 10 per cent., the mulattos 13 per cent., and the negresses only 3 per cent. with infectious syphilitic manifestations.

While the women arrested and sentenced because of the war activity of the insular officials were in the jails, every effort was made to render them noninfectious in regard to their venereal diseases and to improve their general health which was very bad. The district jails at Arecibo, San Juan, Ponce, and Mayaguez were entirely reorganized for the reception of women only and modern hospital services were inaugurated in charge of competent physicians. In addition, the Commanding Officer of the United States Base Hospital at San Juan inspected the hospitals and the Commissioner of Health of Porto Rico was active and provided a specialist to work at the Arecibo Hospital Jail. The Venereal Officer

of Camp Las Casas[4], [5] was deeply interested and took an active part in the diagnosis and treatment of the women affected with venereal disease and diseases of the skin. The Field Director of the American Red Cross for Porto Rico and the Virgin Islands[6] was alive to the question of the relation of the health of the soldier and the freedom of transmissible diseases in the public women, and he furnished, through the Headquarters of the organization, arsenobenzol (606) and transportation for the Officer to administer the drug. More than 1,400 intravenous injections were given to the syphilitic patients and more than 5,000 injections of mercury. The blood Wassermann was repeated after the courses of active treatment were completed in those instances where the patient was still under our care, and in almost half the cases the Wassermann was changed from four plus positive to negative. In 12 per cent. more, the Wassermann was reduced, but in the remainder the Wassermann was not affected. We gave the most intensive treatment possible[7], [8], [9] and followed up each course of salvarsan with the necessary mercury to a degree that we are certain that cures were permanent in most cases in which the Wassermann was reduced. Probably if we could have had the patients under observation sufficiently long to repeat the course, more cures would have been effected. As it was, no case left the institution in an infectious state. Dr. Yordan, writing of the Jail at Ponce, typifies all the jails:

> The women received in six months what they could not receive outside in two years. One of the reasons for this was that we had control of every case and they reported for injections every day, which would be impossible in private practice. The physician in private practice is confronted with the fact that he cannot make a patient continue treatment persistently. We have been able to push the treatments to the utmost and we get better results than in private practice. We would not have so many chronic invalids in society had they received the intensive antisyphilitic treatment these women are getting. Not a woman here could have afforded to receive in private practice the treatment she has received while in this institution.
>
> We know that we have saved many from death that is directly traceable to syphilis; we hope to have removed many more from the road to chronic invalidism; and we have, furthermore, diminished the chances of having these women give birth to syphilitic children. We received women from communities where they were disseminating infectious and contagious diseases, and when released they are noncontagious and noninfectious, and many of them permanently cured.
>
> The patients have all gained in weight, have better complexions, and their general condition is better than when they were admitted. This is due to (*a*) a change in living conditions, (*b*) the absence of alcohol, (*c*) the absence of cigar smoking, (*d*) the medical treatment that was directed to their general condition as well as to their local troubles. They have received the best and most modern treatment for their venereal afflictions and the results have been gratifying.

The cases of gonorrhea were most valiantly treated. Discharges ceased, after different periods of medication. In many cases examination after treatment failed to reveal the causative diploccoccus of Neisser, but we are not so optimistic as to believe that we effected complete cures in all of the chronic cases.

Five cases of yaws or framboesia were recognized and treated. The annual report of the Board of Health for 1917-18[10], [11], gives a very interesting historical and clinical account of this disease in Porto Rico, together with photographs of a recent epidemic on the island. Although not ordinarily classed with the social diseases, yaws is very easily transmissible from one person to another through contact of a lesion to the broken skin surface of a healthy person.

Two cases of an heretofore unrecognized disease in Porto Rico were diagnosed among the inmates of the Hospital Jails. Ulcerating granuloma of the pudenda[12] is the name of this disease, and it is infectious and almost incurable. One of the patients had this disease seven years, during all of which time she carried on her life as an active prostitute. We did our utmost to cure these patients, using the medication found efficacious by the South American authorities, tartar emetic. Unfortunately, the cure takes years rather than months, and we had to release the girls before rendering them harmless. One of the patients was transferred to the Municipal Hospital at Arecibo and the other advised to apply for admission to the Quarantine Hospital at San Juan.

Scabies, ringworm, hookworm, lice, etc., were all treated. Patients were vaccinated against typhoid and smallpox. Several pregnant women were delivered, and miscarriages in others were given necessary care.

The influenza epidemic gave the doctors and nurses more work to do, but the strict quarantine measures limited the ravages of the disease, and the death rate was negligible.

Minor nervous disorders were common, and several cases of actual insanity were properly disposed of.

The teeth were taken care of by qualified dentists, which made the injections of mercury less likely to lead to mouth trouble.

While in jail, teachers were provided for the ignorant. Courses in lace-making and sewing were given, and in many instances the girls were able to earn some money by the sale of their work. This reconstruction effort was nobly performed by the Social Service Committees of the towns in which jail hospitals were situated.

That the main source of infection is the prostitute, and that with her isolation new cases of syphilis among the men of the community and from these to the women and children cease, was definitely proved in Porto Rico.[13] The repressive measures made it difficult for the prostitute to ply her trade.

After six months in camp during which time the number of enlisted men rose from 250 to 12,000, only 20 new cases of venereal diseases were acquired, of which four were syphilitic infections.[14] We are very proud of this low number among a population so recently under military control.

The beneficial effects of the intensive treatment administered to these women has an everlasting effect. Even, as is not improbable, many return to the life from which they were taken to jail, it may be some time before they are reinfected. In the women treated for syphilis, we consider that about half are so far advanced in the cure

that reinfection may be possible. In the other fifty per cent. of the cases, we are not so optimistic, and these women are considered to be in the latent tertiary stage. The amount of medication administered to them during their enforced hospitalization should, however, prevent any infectious lesions for a long time.

On the other hand, many of the girls, rid of the disease which may have prevented them from returning to a more decent mode of living, will not now be hindered by this cause, and will revert to domesticity without being a danger to all their associates.

The expense of such an undertaking seems large when first considered, but the end results warrant even greater expenditures of money. For each woman rendered noninfectious, a number of men are probably prevented from receiving an infection which takes years to cure and which they may pass to others. While the prostitute is in jail she should be treated with the most modern methods and drugs at our command, that in addition to the penal routine, she have her health restored.

Thanks are extended to the Hon. H. L. Kern and to the many officers of the Department of Justice of Porto Rico for their cooperation and advice, and to the Director and assistants of the Institute of Tropical Medicine and Hygiene, San Juan, P. R., for the execution of the laboratory studies.

Infantile Paralysis in Uruguay.—Escardo y Anaya sums up a serial article as follows: Classical infantile paralysis occurs sporadically in Uruguay and there have been three epidemics—in 1906, 1912-13 and 1916-17, respectively. There can be no doubt that this malady is the Heine-Medin disease of Europe commonly called infantile paralysis. Nevertheless in Uruguay it shows certain peculiarities even in comparison with the same affection in Argentine and Brazil.—*Brazil Medico.*

CANCER DEATH RATE IN NEW YORK CITY DURING 1919.

BY L. DUNCAN BULKLEY, A.M., M.D.,
AND
L. BULKLEY CADY, A.B., M.D.,
NEW YORK.

DURING the past two years the mortality from Cancer in New York City during 1917 and 1918 has been presented by one of the writers, and it is interesting to pursue the subject further, as to 1919; for it is instructive to learn if any progress is being made in the control of this dire disease, which is at all commensurate with that obtained in tuberculosis.

These studies have been made from the Mortality Statistics of 1917, the last published by the United States, and from the weekly reports of the Board of Health of New York City in 1919, compiled from the actual return of death certificates: but, as remarked before, these by no means reveal the true death rate, for many cancer sufferers die from intercurrent diseases, as "The Flu," under which the death is recorded, while in certain cases the diagnosis of cancer is withheld for personal or family reasons.

For the first time since 1906 the cancer death rate per 100,000 population in the United States showed a very slight *decrease* in 1917 (the last report, just issued), 81.6 against 81.8 in 1916, for the average yearly *increase* since 1906 had been 1.02 per 100,000.

According to a special report, just received from Washington, there has been a still further *decline* in the death rate from cancer throughout the United States, that is gratifying, and may be due to wiser views as to treatment, but also partly to the high general death rate due to influenza. In 1918 the death rate from cancer was 79.8, a *decrease* from 1917 (when it was 86.6), of 1.8 persons per 100,000.

In the State of New York the cancer death rate has continued to increase, 93.3 in 1917 against 92 per 100,000 in 1916. In some states it has fallen, but in some it remains very high: thus, Massachusetts 108.3, Vermont 107.7, Maine 105.9, New Hampshire 105.3, California 105.1, in the 100,000 population. Some states have a relatively low mortality, South Carolina 36.8, North Carolina 43, Tennessee 46.6, Virginia 53.3.

The cities naturally show a large mortality, owing to patients coming to them for treatment. Thus, the rates for 1917 are: San Francisco 152 deaths, Albany 150, Cambridge 134.7, Toledo 121.3, Boston 120.5. New York City by this report showed 85.6 deaths per 100,000, from malignant disease in 1917, against 84.5 in 1916.

In New York City the *general* death rate has fallen greatly during 1919, compared to the preceding year, when the influenza carried off so many, the figures being 97,615 for 1918, and only 75,036 for 1919, a difference of 22,579, or a reduction of over 23 per cent.

But the recorded deaths from cancer have *increased* from 4,894 in 1918 to 5,124 in 1919, 230, or more than 4.6 per cent. over the preceding year. This is remarkable and unexplainable, for in 1918

the cancer deaths were only 36 more than in 1917, less than *one* per cent. increase. These 5,124 cancer deaths in 1919, (2,250 males and 2,874 females,) divided by 365 days make an average of over 14 deaths daily from this disease against 13.39 persons dying daily in 1918. The lowest number recorded in any one week was 81, or 11.52 persons, and the highest, the surprising number of 132, or 18.83 daily, in the week ending December 20th: the next highest week ending December 6th, giving 119 deaths from cancer, or 17 average per day. There were 24 weeks in which there were reported 100 or more deaths from cancer.

The recorded deaths from tuberculosis in New York City have *fallen* during 1919 from 8,823 to 7,396, or 1,427, that is 16.1 per cent., while, as we have seen, those from cancer have *risen* over 4.6 per cent., an approach of the two of over 20 per cent. The deaths from tuberculosis were 7,396 in 1919, and those from cancer 5,124, a difference of only 2,182. At this rate of change it will not take many years for cancer to outstrip tuberculosis in mortality.

Of what significance are these figures? Why have not our modern diagnosis, our increased skill in surgical technique and the greater intelligence of the laity on the subject, why have not these all been instrumental in staying this dread disease?

Is it not true that present current methods of treating this disease have been found wanting in a large proportion of the cases? And that just as amputation of the gouty toe would fail to cure, so have many of the present methods in treating cancer been disappointing!

That the constitutional treatment of cancer is a vital matter, the writers firmly believe; and they feel that when this aspect of the disease is more widely accepted, progress in its therapeutics will be more rapid, and the mortality from cancer will be materially reduced.

SERUM SICKNESS TREATED WITH PROTEAL.

By F. TWEDDELL, M.D.,

GREAT NECK, N. Y.

On November 20, 1919, E. A. D., aged 30, came down with lobar pneumonia, pneumococcus type I. November 22, 1919, he was given 100 c.c. serum intravenously, and on November 23, 95 c.c. On December 2, he developed a rash which had almost disappeared by December 10 when an acute general arthritis manifested itself, involving nearly all the joints, especially the shoulders, hips, knees, ankles, and wrists, which were hot, red, swollen, painful, and tender. This attack almost subsided and the patient was able to get about slowly, when on December 21 there was an acute exacerbation of all symptoms and practically every joint in the body was involved, including the joints of the fingers and toes and even the temporo-mandibular joints, and the patient was in extreme pain for days. The rash came out for the second time.

By January 8, 1920, the patient was able to get about, but still suffered pains, especially in the shoulders, hips, and knees. On this day I gave him ℞5 proteal No. 39 (alfalfa seed) obtained through the kindness of Dr. Henry Smith Williams of New York. On January 9 the patient reported that he felt no pain a few hours after the first injection, but he noticed a few twinges in the shoulders for a few minutes about two hours before coming to the office this day. He was then given ℞8. January 11 patient stated that he had had no pain or discomfort since last injection. Given ℞10 this day. January 15, has had no symptoms, given ℞10.

The first three doses of proteal were given at 8 P. M. and each night the patient was kept awake for several hours and could not get to sleep. The fourth and last dose was therefore given in the morning and the patient went to sleep that night without difficulty.

I wish I had decided to use the proteal earlier, as I believe the foreign vegetable protein would have neutralized the horse serum, and the patient might have been spared very much suffering. Salicylates and sodium bicarbonate were previously given by mouth and by rectum but did not modify the symptoms.

I hope this experience will be the means of helping other patients developing arthritis after injections of serum and that physicians will give the proteal a trial, as it can do no harm.

Medicolegal Notes.

Disease Resulting from Accident.—In an action on an accident policy, the Texas Court of Civil Appeals holds that evidence that the insured had no hernia previous to his fall while attempting to alight from an automobile, that a hernia developed just after the fall, and a doctor's opinion that in all probability it was due to the fall, justified the jury in finding that the accident was the sole cause of the injury, "exclusively and independently of all other causes," within the policy provision.—Metropolitan Casualty Ins. Co. v. Edwards (Tex.) 210 S. W. 856.

Validity of Quarantine Regulations.—The District Court of Appeal, Second District, California, holds that the adoption of measures for the protection of the public health is a valid exercise of the police power of the state, as to which the Legislature is necessarily vested with large discretion, not only in determining what are contagious and infectious diseases, but also in adopting means for preventing their spread, as by imposing on the health department of a city the duty, when having knowledge that one is afflicted therewith, of taking the necessary measures to prevent its spread. The court holds that a woman with gonococcus infection, declared by the California statute to be infectious, who was originally taken into custody without warrant, but who submitted to examination, is not entitled to habeas corpus to release her from quarantine in a hospital where she was confined for treatment. It is also held that one infected with a contagious disease, declared to be such by the said statute, may be subjected to quarantine regulations by the health commissioners of a city, without its first being judicially established by some proceeding in court that he or she is so affected. —Ex parte Johnston (Cal.) 180 Pac. 644.

Hypothetical Questions.—In a cross-action for malpractice it was held that the fact that a hypothetical question did not contain certain important facts did not render it erroneous where it did not appear that their recital was necessary to enable the expert to form and express an intelligent opinion upon the matter at issue, particularly since additional facts may be brought out in the cross-examination. Objection to a hypothetical question for failure to contain essential facts must specify the additional facts which ought to have been included. It is held better practice to eliminate from a hypothetical question directed to a physician statements not bearing on the treatment and the question should not call upon the witness to interpret the meaning of statements which should be interpreted by the jury.—Dameron v. Ansbro (Cal.) 178 Pac. 874.

MEDICAL RECORD.

New York, March 20, 1920.

ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.

IN his letter of transmission to the Secretary of War, Brigadier-General Merritte W. Ireland, Surgeon-General United States Army, submits a two-volume report containing statistics for the calendar year 1918, and the account of the general activities of the Medical Department, together with the financial statement for the year ending June 30, 1919.

In a war of such proportions as the one from which the world is just now emerging the contemplative mind was fairly staggered by the prodigiousness of the undertaking, while the mind given to "snap shot" judgments was inclined to estimate the whole by the more or less obscure understanding of a part. It is well, therefore, "when the hurly-burly's done, when the battle's lost and won" to have some concrete and tangible gauge by means of which those who have maintained the attitude of suspended judgment may form a just conclusion, and by which the short-visioned diagnosticians may correct or modify their findings.

So far as the activities of the Medical Department during the World War are concerned, the report of the Surgeon-General provides such an instrument. Even a cursory review of the two volumes, which cover the activities of the department at home and overseas, will serve to impress upon the reader the enormity of the undertaking and will cause him to marvel at its successful inauguration, prosecution, and culmination, especially in the light of all the circumstances involved. For, as the Surgeon-General reminds us, the period covered by this report and that which preceded it has been one of the most memorable in the history of this country. It has witnessed the inauguration, the full development, and the successful ending of the unparalleled activities of the War Department and of the nation as a whole. We are reminded by contrast, that during the Civil War the maximum strength of the United States Army, including both Regulars and Volunteers, was approximately 860,000, of which number 300,000 were absent from duty for various causes. The maximum forces for the United States Army, excluding the Navy and Marine Corps, were, in October, 1918, over three and a half millions. At the beginning of 1917, or practically at the beginning of the war, the strength of the army was less than 100,000. To increase this small army to one of over three and one-half millions, properly to clothe, equip, and train it, and to transport something over 2,000,000 soldiers with all the necessary modern equipment, supplies, and transportation to the battlefields in Europe, over 3,000 miles of submarine-infested ocean, was, as the Surgeon-General states and all must agree, an undertaking worthy of the efforts of a great nation. The process of devolution, so to speak, was no less wonderful than that of evolution. The safe return of practically all of this immense army to home and peace-time pursuilts was accomplished with such expedition and facility as to cause unstinted admiration and congratulation for all concerned—which means the country as a whole.

The part played in this great drama by the Medical Department of the army and the medical profession of the country is partially outlined by the Surgeon-General in this report. Again figures serve to indicate the herculean task which the Medical Department faced when this country entered the war. At the beginning of the war the entire Medical Department, including commissioned officers, contract surgeons, army nurses, and civilian employees, numbered 8,634. This personnel, according to the report, reached a maximum of 354,796, almost three times the strength of the entire army a few years before the beginning of the war. The Medical Corps increased from 833 to 30,591; the commissioned ambulance service from 0 to 209; the Commissioned Dental Corps from 62 to 2,002; contract surgeons from 181 to 939; the Commissioned Sanitary Corps from 0 to 2,919; the Army Nurse Corps from 403 to 21,480; the enlisted personnel from 6,619 to 281,341; civilian employees from 450 to 10,695. The hospital facilities of this country had to be expanded from the needs of an army of less than 100,000 to the needs of one of nearly 2,000,000. In the American Expeditionary Forces it was necessary to provide hospital accommodations not only for the usual percentage of sick and injured, but also for the great number of wounded. There sprang into existence from nothing a total of about 300,000 hospital beds, including the emergency beds and those in convalescent camps. At the time of the armistice a little less than 195,000 of these beds were occupied.

These facts and figures, which give but a flash-light impression, serve as indicators. One must go further to appreciate fully the splendid achievements of the Medical Department. The Surgeon-General has given an admirable survey of the whole prodigious undertaking of weeding out the unfit, keeping the fit in condition to fight, and bringing the sick and wounded back to health. The complete details of this accomplishment in all the departments of this great establishment must of necessity be awaited until the full account—the Medical and Surgical History of America's participation in the world war—is published—as we assume it some time will be. In the meantime, this report

should serve to dispel any lingering vestige of "A. E. F. grouch," of which one heard enough a few months ago, and should serve to stimulate enrollment in the new Medical Reserve Corps.

TREATMENT OF SOME CHRONIC PROCESSES BY BACTERIOTHERAPY.

When certain affections of the digestive tract, as well as those of the respiratory, circulatory, and nervous systems, and skin, such as gastrointestinal disturbances, emphysema, arteriosclerosis, asthma, dermatoses, etc., are considered they will be seen to be manifestations of the same process whose characteristic is precisely the slowness of its evolution and incurability designated under the term of chronicity. The intercurrence of these various chronic affections would seem to indicate an identical causal entity in all these cases. From the humoral viewpoint this chronicity is a manifestation of a chronic state of anaphylactic hypersensibility. We know that an acute infection produces a reaction with a double manifestation in the organism—a state of increased resistance or immunity and a state of diminished resistance or increased sensibilization known by the name of anaphylaxis. This hypersensibility—requiring special conditions for its appearance—has been more particularly described in its acute manifestations after inoculation of the causal factor; in other conditions this state exists in a chronic way but in a different form.

In this respect, it is of interest to recall Danysz's experiments. If horse serum is injected in small doses in the rabbit and repeated for twenty or thirty days, an attack of anaphylaxis will never be observed although the serum will be precipitating after the fifteenth day. If the animal is left alone after these injections, nervous symptoms—pareses—will appear in two or three months, or else dermatoses with alopecia, rheumatism, etc., will develop, if no other infectious disease intervenes. Similar phenomena occur in horses immunized intensively for producing antitoxic or antimicrobic sera. The animals are less active and vigorous and often die from internal hemorrhages or ruptures of the liver. These morbid states recall the functional disturbances of what is called chronicity.

In the above experiments, everything appears as if the reactions of the organism against an antigen were in play. Now, the lesions found at an autopsy of these animals immunized against toxins show an intense functional activity of the viscera and increased hyperplasia of the hemolyph organs—spleen and bone marrow, manifest evidence of hypersecretion of the endocrine glands—which indicates a hyperactivity of the cells, the function of which is precisely the production of antibodies. The superproduction of antibodies overworks the cells. The same process occurs in man, with this difference that the production of antibodies occurs only as rapidly as the introduction of antigens into the organism takes place. These are always present at the point of entrance in the form of intestinal bacteria and incompletely transformed albuminoid débris. If now a very trifling disturbance of the physiological integrity of the intestinal mucosa arises, these agents at once invade the organism in variable quantities. The tissues resist the first shock—there is active immunity. The period of immunity begins, then a state of slow anaphylaxis and develops gradually for a certain length of time, but with the second attack the anaphylactic crisis will be more or less sharp.

These manifestations are not necessarily clinically in evidence from the start and the patient's condition may be overlooked. Everything takes place in the depth of the body, hence the origin of cell disturbances which goes on increasing and finally becomes apparent. The clinical manifestations are quite as varied as in animals; at first mild—temporary congestion, pruritus without apparent cause; then dermatoses, asthma, gastrointestinal disturbances, rheumatic attacks, etc., make their appearance year after year in succession. It is consequently important to determine the origin and nature of the antigens capable of provoking this anaphylaxis. The skin is not easily invaded so that the cutaneous bacteria are unimportant from this standpoint. On the other hand the bacteria of the intestines play an important part, but it is to be remembered that these intestinal antigens are multiple, they are not only represented by bacteria, but by their secretions as well, or albuminoids of alimentary origin which have been incompletely transformed—polypeptids, albumoses, peptones—in opposition to which the organism is also in a state of latent anaphylaxis.

The treatment of these disturbances should first be to reinforce the digestive power by proper diet, but the curative treatment should be antianaphylactic. This consists in neutralizing the ill-effects by the exhibition of small doses of appropriate antigens, namely, the intestinal flora derived from the patient's stool. These are isolated, cultured, and then sterilized at 60° C. This vaccine is given per os—two to three milligrams of microbic bodies, or preferably subcutaneous injection—an emulsion for twenty-four hours comprising one to two hundredths of a milligram of microbic bodies. This treatment is not a vaccination producing a specific immunity because there is no specific causal agent at work. Its action is more like that of proteosotherapy, lymphotherapy, or autoserotherapy. As Widal, Abrami, and Brissaud have shown, in utilizing autoserum in asthma or paroxysmal hemoglobinuria, a specific antibacterial action is not in play but the outburst of an anaphylactic crisis, the first shock of which is hematic, a physicochemical disequilibrium is avoided. In cases in which this bacteriotherapy has been resorted to the results seem to be encouraging.

THE RELATIONSHIP BETWEEN INFLUENZA AND TUBERCULOSIS.

Influenza may, as has been frequently asserted, cause a lighting up of tuberculous manifestations in subjects who have apparently recovered from a former tuberculous infection. This awakening of a tuberculosis upon the occasion of a grippal infection recalls by its symptomatology that which takes place after other infectious processes in general. The signs may be given in the order of their appearance as follows: presumptive signs represented by the hereditary antecedents of bacillosis; signs of probability made evident by a long drawn out convalescence, a low blood-pressure, the reappearance of the fever which is irregular with oscillations, the persistency of the cough accompanied by a free expectoration, a progressive decrease of the physical strength which takes the place of the increase occurring in convalescence from an uncomplicated influenza. The sign of certitude is given by the presence of the tuberculous bacillus, so that a systematic examination of the sputum should always be carried out in cases of convalescence from influenza which do not frankly recover, but drag on. It should be understood, of course, that the awakening of a tuberculous process must not be mistaken for influenzal manifestations simulating tuberculosis on account of their development at the pulmonary apex and giving rise to hemoptysis which so frequently accompanies the pulmonary lesion. Hence the importance of laboratory examination of the sputum. It is of great importance not to misconceive the situation, because a fresh development of a tuberculosis must be dealt with vigorously and with no loss of time since the soil has been weakened by the influenza and consequently is less resistant to the bacillus of tuberculosis.

It is known that tuberculosis developing in the adult is usually an explosion of an old latent process, because man acquires by tuberculization a relative immunity—a kind of autovaccination. Now, when the subject contracts an infectious disease, his immunity becomes less and the organism may even present a state of antianaphylaxis, especially when the infection is as weakening as is influenza; hence the return to activity of incompletely cicatrized lesions. At the same time that organic resistance is lowered it is quite possible that a hypersensibility may exist in a tuberculous subject—a sort of anergy results from the new infection. The microbic associations are also not indifferent to this process as this association increases the virulence of the bacillus, therefore adding its very marked congestive action to epithelial desquamation which results in and consequently favors the development of the lesions. But although the associated microbic agents of influenza may exert a stimulating action upon the bacillus of tuberculosis, some data seem to show that, in other conditions, tuberculous subjects may possess a kind of indifference towards the grippe, and although apparently contradictory these can be fairly well explained. It would seem that to a certain extent these subjects are refractory to influenza, as has been shown by Bricaire, Bezançon, and Guinard. In progressing tuberculous cases influenza seems to be infrequent and is more prone to develop in patients with a mild tuberculosis. Marfan is of the opinion that tuberculous patients offer a certain immunity to this epidemic affection. That this may be the result of parabacillary microbic associations is possible. Cornil, Babes, Mosny, and Aviragnet have shown the frequency of pneumococci around foci of tuberculosis, while Veillon that of other bacteria—the streptococcus, staphylococcus, and pneumobacillus. There is no reason why individuals with such lesions should not offer a certain resistance to an infectious process whose etiological agents are the very ones encountered in influenza, at least in its more serious and complicated forms. On the contrary, in cases of long standing tuberculosis in which Koch's bacillus is asleep in the midst of a cicatrized lesion, the associates of the bacillus will have returned to their modest rôle of saprophytes.

MEDICAL MISSIONS AND THE PEKIN UNION MEDICAL COLLEGE.

Medicine as introduced by western missionary doctors into the non-Christian countries of the East, has recently undergone changes which are both interesting and important. At first its emphasis was necessarily quantitative. A pioneer medical missionary like the great Dr. Joseph Plumb Cochran of Persia treated many thousands of cases a year. Even recent figures showing the numbers treated in the mission clinics and hospitals would stagger the busiest of similar institutions in this country. Of course thoroughness was sacrificed to numbers. But within certain limits hasty treatment is better than no treatment—certainly better than magic and incantations.

Gradually—or rather (considering handicaps) with remarkable rapidity, the missionary hospitals and medical schools have provided natives trained in at least the essentials of modern medicine. The missionary colleges in China now stand ready to offer the premedical courses for a medical school which bids fair to be second to none in this country, namely, the Pekin Union Medical College. This is an institution with which the profession should cultivate a close acquaintance. It owes its existence to two factors: the pioneer work of the medical missionaries, and the philanthropy of Mr. Rockefeller, so wisely carried out, in certain directions, by the Rockefeller Foundation. The teaching personnel has been selected in large part from the highly trained workers of the Rockefeller Institute. They will have the double task of instruction and investigation—and clinical material they will have in superabundance.

The missionaries have been hampered by overwork and by inadequate funds. The staff of the

new school at Pekin will have plenty to do. They will also have means and equipment with which to do it. Their results will probably be much more sensational, at any rate from the scientific point of view, than those of their medico-evangelical colleagues. But, far from overshadowing the missionaries' work, they will really serve to indicate its intrinsic value. If the venture at Pekin is a success, as it undoubtedly will be, similar institutions for instruction and research will in all probability be established in other distant lands, whether or not by the Rockefeller Foundation. Such enterprises should be welcomed and their growth fostered by the profession at home.

THREE BAD BILLS.

THE New York Legislature has now under consideration three bills relating to the medical profession in this State, and three worse bills could hardly be conceived of. One of these is the revived Davenport bill for compulsory health insurance. It is unnecessary to review that, for the profession in this State is now familiar with its chief features and has condemned it with practical unanimity. It legalizes the worst features of the old lodge practice, and all that it insures is, in general, poorer treatment of the sick wage earner than is now at his command with or without fee.

The second of these vicious bills is that known as the Gibbs bill, which purports to provide a greater degree of narcotic drug control than is now afforded by the national and State drug laws. An ordinary man's house is his castle and cannot be broken into without a warrant except in an emergency, to prevent crime or to capture a criminal, but under this bill a doctor's house can be entered at will by the commissioner of narcotic drug control who may, if he wishes, delegate this task to one of his deputies or inspectors. And when the house has been forcibly entered the inspector may pry into every bureau drawer or private desk on the bare suspicion that a morphine tablet may be lying around somewhere.

The third attempted invasion of the physician's rights is provided for in the Kenyon medical license bill, which calls for annual licensing after examination of the doctor's credentials, filing of his photograph, and payment of a $2 fee. Without all this vexatious and humiliating tomfoolery the practitioner of twenty or thirty years' standing will be denied his right to follow his calling and will be put on an equality with the advertising venereal quack, or the unlicensed beauty doctor.

With the physician being forbidden to prescribe a necessary drug until he has done enough paper work to gladden the heart of an army surgeon, and broken the law by revealing professional secrets; being restricted to the dose of an ounce and a half of brandy a day in a case of prolonged sepsis or pneumonia; being liable to the invasion of his house by a drug commissioner's deputy who may without reason suspect him of hoarding morphine; and being forced to buy each year the privilege earned decades ago of practising his one-time honorable profession, the doctor's rights to life, liberty, and the pursuit of happiness seem to be not altogether unalienable.

CODEINE POISONING.

FATALITIES from the use of codeine are so rare that so recently as 1910 von Jaksch said that he knew of no case of this sort, although in 1906 Brouardel had reported one in a child of sixteen months. In 1919 MacNally of Chicago mentioned three deaths in Cook County during the period of 1905-1917 without giving details. Cases of codeine poisoning with recovery seem equally rare. All in all we know little of the toxicology of this alkaloid. Boissonnas in the *Revue médicale de la Suisse Romande* for December, 1919, xxxix, 12, relates in detail a case of this nature in a child aged three years. The case was due to an accident in which 4 cgm. of codeine was given by mistake for calomel. The powder was swallowed at half past seven in the morning and there was no action observed until three-quarters of an hour later when the child complained of violent headache, which was promptly followed by convulsions and coma. The author was summoned and found the pupils contracted to the limit, the neck rigid, the head thrown back, and the pulse imperceptible. The heart was beating at 120 with clear sounds. An injection of camphor oil was given and followed by a rally, consciousness returning and the pulse becoming perceptible. Wet cups were applied over the loins and the patient was made to drink freely. The alleged calomel from the apothecary's was hurriedly sent out for analysis and camphor injections were repeated. At a quarter of ten the patient had a crisis of rigidity and executed swimming movements with the arms, again losing consciousness. By eleven o'clock he had become relaxed and appeared to be asleep with normal respiration. The earliest report from the laboratory was that the supposed calomel was an alkaloid, nature not yet determined. The addition of milk sugar complicated the analysis. In the meantime the apothecary who dispensed the prescription confessed his error and told the nature of the alkaloid. At four P. M. the condition of the patient was encouraging save for complete anuria. A catheter could not be passed and 400 c.c. of urine was drawn off by aspiration. In a few days recovery was complete.

CHROMIUM SALTS AND PERFORATION OF THE NASAL SEPTUM.

AMONG the diseases and stigmata of occupation perforation following ulceration of the nasal septum is well known, but details in these affections are not always forthcoming. Ranielletti, an Italian physician, whose original article is abstrated in *La Presse Médicale* for December 20, 1919, xxvii, 78, has recently studied the subject at first hand in a bichromate of potassium factory. He reports that the lesion is as characteristic as is phosphorus jaw in match workers. The workmen in the factory inspected showed ulceration in 56 per cent. and perforation in 15 per cent. In addition, there are fre-

quently, but by no means always, preliminary catarrhal discharge and epistaxis. The seat of the ulcer and perforation is the area—as was experimentally shown—where the fumes and débris impinge on the septum. This is at the lower portion of the cartilage and more often anterior than posterior. The ulcer is small—no larger than a lentil—with clean-cut margin and of a grayish color. It is often bilateral. Unless treated, perforation inevitably results. The ulcer is perfectly circular, with reddened border. It gives rise to no symptoms, and this silence is doubtless the reason for the slight rôle it plays in occupational pathology—in other words, it is better regarded as a stigma of occupation than a disease. Moreover, in the ulcerative stage it is easily cured while in general it is a condition which is quite preventable if one takes the trouble. The worker should wear a piece of salicylic gauze in the nostrils while occupied. If this is burdensome application of zinc oxide ointment may be recommended. After the ulcer has appeared cauterization with nitrate of silver stick will prevent perforation. The real management, however, must deal with the problem of dust and vapor in the workshop.

Beriberi as a Mask for Other Affections.

It seems inevitable that in countries in which beriberi is a scourge other chronic cachectic affections may be wrongly diagnosticated. Thus Doctor Bobeau of Saigon relates a case in which the diagnosis was "abortive form of beriberi." A colleague of the author thought that the case resembled Addison's disease and obtained an autopsy, in the course of which he found lesions of the adrenals, and sent slides to the Society of Comparative Pathology for microscopic study. In a second fatal case Bobeau likewise dissented from the diagnosis of abortive beriberi in favor of tuberculosis, and autopsy revealed an enlarged tuberculous mesenteric gland. These two cases open up a field which may prove to be very extensive. It seems especially likely that a typical tuberculosis may mask as beriberi. A writer in *Le Caducée* for January 15, 1920, xx, 2, takes exception to these strictures by Bobeau upon the trustworthiness of the French Colonial Office in regard to dealing with medical problems and the need of an independent medical mission; he regards the medical men in charge of sanitation in Saigon as fully qualified to deal with questions like masked beriberi.

Contagion of Rheumatism.

Grenet believes that acute articular rheumatism may sometimes be contagious. Aside from cases in which one case is followed by others there are examples in which some other infection appears to give rise to acute rheumatism and vice versa. This possibility is not so remote as might at first sight appear. Thus acute rheumatism may be preceded by angina and an angina may be contagious, with the result that another subject contracts it and also develops rheumatism like the first. But the possible contagion of rheumatism is no new theme and many well-known clinicians have upheld it, among them being Mantle, Thoresen, Feldkamp, Friedlander, Edlefsen, Fiessenger, and Monnier with Leclerq and Pierret. The author, writing in the *Gazette des Hôpitaux*, reports the case of a healthy soldier who developed acute articular rheumatism, and six days later those next to him on either side in the ward developed the disease. Again, a convalescent from pneumonia placed next to a subject with acute rheumatism himself developed the latter disease.

News of the Week.

Newark Handles Whiskey Problem.—Newark druggists have been profiteering on whiskey to the tune of of $7.50 a pint. The City Dispensary, by order of Mayor Gillen, as head of the city health department, sells it at the rate of one dollar a pint. It is obtainable on physician's prescription, and each patient, under the law, is permitted to purchase a pint every ten days.

Nurses Graduated.—The Margaret Fahnestock Training School for Nurses, of the Post-Graduate Medical School and Hospital, New York City, graduated fifty nurses March 9. Plans are being made for additions to the School for Nurses on adjoining property, recently purchased.

Fire in Ohio Hospital.—Seven male patients lost their lives in a fire, thought to be of incendiary origin, in the Ohio State Hospital for Epileptics at Gallipolis, March 9. Three other patients were in a serious condition from inhaling smoke.

Saleswomen Pro Tem for Charity.—Fifty prominent women in New York City have been working as saleswomen in a local department store in the interest of the Social Service Bureau of Bellevue Hospital. Ten per cent of their sales will be received by the women, who will turn the money over to the hospital.

Plague Warning Sounded. — Surgeon-General H. S. Cumming, newly appointed head of the United States Public Health Service, who has just returned from overseas, warns against the possibility of bubonic plague and typhus fever being brought into the United States from the Levant. Dr. Cumming has been making a tour of investigation, visiting every country except Bolshevist Russia. Precautions should be taken, he says, at the ports of embarkation in the Mediterranean, which would necessitate an increase in the force of United States health officers abroad for the purpose.

World Child-Welfare Movement.—During the recent convention of the League of Red Cross Societies at Geneva a campaign for child welfare was agreed upon which, it is thought, will profoundly affect child life and the health and care of mothers throughout the world. It is proposed to make the plan immediately effective everywhere when once it is in operation.

Milk for Italy.—The American Free Milk and Relief for Italy shipped 10,000 quarts of dry milk to Italy last week for the relief of destitute children. It is announced that the organization will increase its shipments from 60,000 to 100,000 quarts of dry milk a month.

Grave-Diggers Strike.—News comes from Berlin that great inconvenience has been caused by a strike on the part of grave-diggers. The rela-

tives of the deceased have had to dig graves themselves in many instances.

Canadian Hospital in New York City.—Members of the Canadian Club in New York City are planning a campaign to raise $1,000,000 to build and equip a Canadian hospital in this city. Committees will be appointed to direct the drive.

Aid for Middle Europe.—At its recent convention in Geneva the Board of Governors of the League of Red Cross Societies, acting upon an appeal by Arthur J. Balfour as President of the Council of the League of Nations, passed resolutions declaring for the extension of voluntary relief work among the starving and diseased populations of Central and Eastern Europe, with the proviso that the essentials of food, clothing and transportation be previously assured these peoples through Governmental action.

The Harvey Society.—The eighth lecture of the series will be given on Saturday evening, March 27, at 8:30 o'clock, by W. McKim Marriott, M.D., Professor of Pediatrics, Washington University, on "Some Phases of the Pathology of Nutrition in Infancy."

Bacteriologist-Pathologist Needed by New York State Department of Health.—The New York State Civil Service Commission announces an examination to be held April 10 for bacteriologist-pathologist. The salary is $2500 to $3000; the age limits are 25 to 45 years.

Dr. William Wesley Carter has removed his office to 2 West Sixty-seventh Street, New York.

Dr. Charles Winfield Perkins has removed his office to 180 West Fifty-ninth Street, New York.

Compulsory Insurance Again.—The compulsory insurance bill was introduced in the New York State Senate last week under the name of "Illness prevention and illness insurance for industrial workers." The new bill provides that employees and employers shall share all expenses and manage the illness prevention and insurance system through a board of directors selected by themselves, half from each side.

Brooklyn Doctor Violates Volstead Act.—The first arrest of a physician in Brooklyn for violating the Volstead Act was made last week. The offender was alleged to have issued five prescriptions for one pint each to one man in thirteen days, which would certainly not be an excessive amount in certain cases of sepsis.

Welch Memorial Volumes.—The seventieth birthday of Dr. William H. Welch, of Baltimore, which occurs in April, is to be signalized by the publication of his various papers and addresses in three volumes, to be issued from the Johns Hopkins Press, under the editorial supervision of a committee. The set of three volumes, bound in linen, is offered to subscribers for $16.50. The edition will be restricted to the number subscribed.

The American Posture League at the annual business meeting held on Saturday afternoon, March 13, elected the following officers: *President*, Jessie H. Bancroft; *Vice-President*, Dr. Frederick R. Green; *Secretary*, Dr. Henry Ling Taylor; *Treasurer*, Dr. George J. Fisher; *Executive Committee*. Jessie H. Bancroft, Dr. Frederick R. Green, Dr. Eliza M. Mosher, Dr. George J. Fisher, Dr. Henry Ling Taylor. The annual public meeting for the League has been postponed to the week of April 5 when the American Physical Education Association holds its annual convention in New York.

Obituary Notes.—COLONEL LOUIS A. LA GARDE, Medical Corps, United States Army, retired, of Washington, D. C., died March 7, of apoplexy while en route from Chicago, where he had been attending a meeting of the National Board of Medical Examiners, of which he was secretary. Colonel La Garde, who was born in 1849, was graduated from Bellevue Hospital Medical College in 1872, and entered the service in 1876. He had contributed to medical literature, especially that of war surgery, being the author of a well-known work on "Gunshot Wounds." He was instrumental in securing the adoption of the heavy calibre automatic pistol now used by the army.

Dr. SILAS BLAISDELL HULL of Brooklyn, N. Y., died March 6. He was graduated from the Long Island Medical College in 1916, and served in the United States Navy during the war as a senior grade lieutenant in the mine-sweeping service in foreign waters. He was a member of the Kings County Medical Society, the Association of Military Surgeons of the United States, and other organizations.

Dr. PETER LAWRENCE SCHENCK of Brooklyn, N. Y., died March 6, in his seventy-seventh year. He was graduated from the College of Physicians and Surgeons in 1865. After his graduation Dr. Schenck enlisted in the Civil War, and served until the close of hostilities. He was at one time assistant surgeon and later medical superintendent of the Kings County Hospital. He was not in active practice at the time of his death. Dr. Schenck was a member of the Kings County Medical Society, the Brooklyn Pathological Society, and other organizations.

Correspondence.

CALCIUM THERAPY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Were it not for the sinister implications, the communication from Dr. Meltzer (MEDICAL RECORD, March 6, 1920) would require no reply. To the quotation from my article he adds a "rider" and then fights the rider. At this interview not a word was said about intraspinal administration of calcium salts for threatened collapse incident to the intraspinal use of magnesium sulphate. The latter method of administration was then confined to hospitals and like institutions, and intravenous medication was but rarely employed, at least by the general practitioner. I had in mind to give the calcium salts internally, as their employment in this manner during the preceding seven years had produced such uniformly good results. Evidently, Dr. Meltzer's statement was a subconscious verdict, for he now says, emphatically, "that the dose of the solution of calcium salts *must be only moderate*, since large doses of calcium following injections of magnesium may prove to be deleterious for the heart. This warning is based upon many incidental experimental observations." And he naively adds, "But they were made only in recent years

and the nature of the deleterious action was not yet studied experimentally."

Perhaps I can refresh Dr. Meltzer's memory by an incident. When I mentioned the remarkable results attending the experimental investigations carried out by Dr. Oscar Loew, of the United States Department of Agriculture, he said he knew Dr. Loew very well, that he was professor of chemistry in the University of Munich before coming to this country, but he corrected my pronunciation of the name, said it was pronounced Lœf.

Now, my theory of "magnesium infiltration" is based upon Dr. Loew's demonstrations in plant life, as follows: "The calcium nucleoproteids of the organized structures are transformed by the presence of soluble magnesium salts into magnesium compounds, while the calcium of the former enters into combination with the acid of the magnesium salt. By the transformation of organized nucleoproteids into magnesium nucleoproteids the capacity for imbibition will change, which must lead to a disturbance in the structures that will prove fatal. Only the simultaneous presence of dissolved lime salts can prevent this effect, according to the law of mass."

JOHN AULDE, M. D.
1024 WALNUT STREET, PHILADELPHIA.

ENCEPHALITIS ALETHARGICA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Noting the editorial note in the last issue of the MEDICAL RECORD on sleeping sickness, I wish to call attention to a condition which I have named "encephalitis alethargica."

The patients have various symptoms of sleeping sickness: more or less severe pains in head, neck, limbs, and abdomen. The temperature, however, ranges low, usually about 99° to 100° F., occasionally to 101°. Vertigo is prominent and in about 60 per cent. of cases, ocular symptoms develop about the third to fifth day, the patient complaining of "double vision." Occasionally there is some cyanosis.

The most prominent complaint, however, of the patient and attendants is inability to sleep. Opiates, bromides, and chloral seem to have little or no effect. In fact, opiates seem to have very little effect on any of the various bodily pains.

The pulse is slow, as a rule, easily compressible, and no dangerous condition seems to arise, except a moderate degree of delirium in the cases with the higher temperatures, averaging 101° F.

After one week a stationary stage is reached and the patient makes no progress either for better or worse.

I would like to hear of the experiences of other men with these cases and would very much appreciate suggestions regarding some treatment which would change the patient's condition from the stationary stage mentioned above.

I have had a series of about sixteen cases and the diagnosis seems to be a very mild form of encephalitis. All cases give a history of more or less definite influenza infection from two to four weeks previous.

EDGAR MORTON WOOLF, M.D.
1383 LEXINGTON AVENUE, NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 27, 1920.

Meeting of the British Medical Association.—The eighty-eighth annual meeting of the British Medical Association will be held in Cambridge on June 29-July 2, under the presidency of Sir T. Clifford Allbutt, K.C.B., F.R.S., Regius Professor of Physic in the University. Arrangements are going forward steadily to make of the meeting a great success. Most of the circumstances seem to conspire to bring about this result. No better or more convenient place than Cambridge could have been selected throughout the length and breadth of Great Britain. It is easily reached from all points, being a great railway center, and is little more than an hour's run by rail from London. It not only has ample accommodation for the large meetings and the meetings of sections, but its hotels and boarding houses can provide for and accommodate comfortably a very large number of visitors. Moreover, the university itself, with its colleges, libraries and various places of interest to the scholar and man of science, will attract many, and it is excellently adapted from the social standpoint for both amusement and instruction. Sir T. Clifford Allbutt, the president-elect, is now the grand old man of the British medical profession, one of the most learned and cultured speakers and writers in the country, and a man whose charm of manner was equaled among the members of the profession only by the late Sir William Osler. The annual general meeting will be held on the afternoon of June 29 and on the same evening Sir Clifford Allbutt will give the presidential address. The scientific sections will meet June 30, July 1 and 2, the mornings from 10 A.M. to 1 P.M. being set apart for discussions, and the afternoon from 3 o'clock for clinical and laboratory demonstrations. The sections this year are twelve in number. The section of medicine, President, Sir Humphrey Rolleston; of surgery, President, Sir George Makins; of pathology and bacteriology, President, Professor Lorrain Smith; of neurology and psychiatry, President, Dr. Henry Head, and of physiology and pharmacology, President, F. G. Hopkins, will meet on each of the three days. The remaining sections, each meeting on one day, are as follows: Obstetrics and gynecology, President, Dr. Herbert Williamson; tropical medicine, President, Professor G. H. F. Nuttall; electro-therapeutics, President, Dr. A. E. Barclay; medical education, President, Sir George Newman; medical sociology, President, Dr. G. E. Haslip; naval and military, President, Colonel Joseph Griffiths, and venereal, President, Mr. E. B. Turner. The popular lecture will be given on the evening of July 2 by Dr. G. S. Graham Smith.

International Health Commission.—The League of Nations Council, which met in London on Feb. 14 last, appointed a committee to draw up a scheme for an International Health Commission. Such a central authority as a commission of this character would necessarily be is greatly needed at the present time. The war has generalized diseases formerly localized, and the easy constant intercommunication of all the peoples of the earth has rendered the establishment of an international health

commission essential to the preservation of the public health.

British Honor for Professor Tuffier. — His Majesty the King has been pleased to approve the appointment of Professor Tuffier to be an Honorary Knight Commander of the Order of the British Empire. As the *Lancet*, Feb. 21, remarks, this recognition of Professor Tuffier's services to the wounded British officers and men brought into Paris during the early phases of the war and of his kindly and untiring efforts to make the Inter-Allied Surgical Conferences a success will be regarded with general satisfaction by all those who enjoyed the pleasure and privilege of working in association with him.

Medical Science and Life Assurance. — It has been suggested recently that a large number of interesting questions will arise if there is established, as many think there may be established, a connection between life assurance and medical science. Of course, there is a limited connection at the present time, but not so useful or so intimate as it might be made. When an office receives a proposal for life assurance it is almost invariably considered advisable for a medical examination to be made. This may take place at the head office of the company, and be conducted by its chief medical officer, or the examination may be made locally, and the company's chief medical officer, perhaps in consultation with the actuary, may decide whether the case is to be accepted as first class, to be postponed, to be rated up or to be declined. It goes without saying that care in the selections of lives is important for a life office, because it determines whether or not future mortality is likely to be favorable or the reverse. When a life office is simply seeking favorable mortality, the use at present made of medical knowledge may perhaps be considered fairly adequate. As Mr. William Schooling points out in an article on the subject in the *London Daily Telegraph*, Feb. 24, all reliance is placed upon the empirical judgment of a medical man based upon knowledge that is only organized to a very slight extent. There is no pretence of trying to obtain the assistance of medical science; and the present methods do not always secure the best possible results from even the art of medicine. Presumably every life office seeks as its chief medical officer the most competent and experienced man that can be found. When a proposer is examined at the head office, as much or as little investigation can be made as the examiner thinks necessary. But when the examination is made by a local examiner, the basis upon which the case is dealt with leaves much to be desired. Sometimes the local examiner is carefully chosen for his medical qualifications, while in some instances the amount of life assurance which the local doctor is prepared to take, largely influences the choice. Even when the medical man with the best qualifications is selected it does not always follow that the fullest use is made of the services he is competent to render. To begin with, there is the somewhat difficult point as to an appropriate fee for a medical examination for life assurance. The transaction is a financial one on both sides. Any doctor will endeavor to save life or alleviate suffering, though he may receive no fee at all, but the information or advice he gives to a life office is based on no such humanitarian sentiment. If the doctor is in error the company may lose money; if he reports fully and wisely it may save money. The life office is likely to receive information and advice which is worth what it chooses to pay, and no more. Some life offices invite the doctors to fill up elaborate schedules of information, and, if the doctor were to do so for the fee he is sometimes offered he would be acting as an ill-paid clerk. Moreover, as the majority of medical men have no belief in the utility of these excessively detailed forms, it may be taken for granted that such information as is supplied upon them is of no great value. As a matter of fact, the question of the fee that a life office can pay is not an easy one to settle. If the premium is small, the medical fee may absorb the whole or a large proportion of the first year's premium. The case may have to be declined, and then the fee is a net loss to the company that pays it. Yet even for policies of comparatively small amounts, no life office, hoping for permanently satisfactory results, will dispense with a fairly careful medical opinion about each life. Conditions in life offices with regard to medical examinations are not so satisfactory as they might be. In Great Britain, at any rate, they appear to be wedded to the old methods, although the war produced some heart searchings. For example, the examination of would-be aviators presented many difficulties, so many indeed, that it was proposed that in the medical examination of these, specialists should be employed by the whole of the offices, and this brings us to Schooling's suggestion that a medical examining institute should be established. According to Schooling, such an institute would quickly bring medical science to the help of life assurance, in place of that medical art of intuitive guessing upon which life assurance at present chiefly relies. Further, while the medical profession, or those members of it who examine for life companies, will hardly agree with Schooling that the results of their examinations are founded upon intuitive guessing, such an institute could do very much more than merely make examinations as a preliminary to life assurance. Regarded as an insurance medical institute, it could systematically examine all policy holders assured in the offices that were maintaining it. They could go every year, or every five years, or whenever they thought fit, to be examined and could be given a report as to their condition and progress. The institute would be equipped with every modern scientific means for making a diagnosis; x-ray examinations could be made, blood could be tested, and thus there would become available the life histories of a large number of cases. A number of cases of cancer might be found. A detailed examination of the early history of all cancer cases might show certain features in common to suggest the way in which it developed, and ultimately, perhaps, a method for its cure. It is undoubtedly perfectly correct to say that it is impossible to overestimate the value to the community of the vast mass of recorded observations that would in time be accumulated by means of scientific medical examinations in an institute of this nature. Up-to-date medical men do not concern themselves solely with the curing of disease, but by discovering the primary causes to prevent it. It is a fact admitting of no dispute that the analysis of systematic examinations of thousand of lives would

go far to facilitate that organization of medical knowledge which would entitle it to be termed medical science.

Probably, however, to expect that life assurance companies, many of those in Great Britain being notoriously conservative, would welcome such a scheme is Utopian, or, at least, premature. That it would be of national benefit seems certain, but it is likely that most of the boards of directors would look upon the matter from a different viewpoint or fear to put a system so contrary to traditional ideas into execution. A plan of this kind seems more apt to receive consideration from go-ahead Americans, and perhaps might be commended to the attention of the British Ministry of Health. In any event, the conception is a fascinating one and in the future, possibly in the near future in America, may be practically realized. Even as an experiment it should be well worth while.

The Professorship of Anatomy at Cambridge.—The General Board of Studies of Cambridge University have recommended that in future the Professor of Anatomy shall receive a stipend of £1,200 a year, of which £350 will be charged on the funds of the department.

Miners' Eyesight.—In a paper dealing with the lighting conditions in mines, with special reference to the eyesight of miners, read at a meeting of the Illuminating Engineering Society, at the Royal Society of Arts, on Feb. 24, Dr. T. Lister Llewellyn said it seemed incredible, but the source of light which gave the highest candlepower at the coal mines was the tallow candle. With the exception of the manufacture and packing of some specially sensitive photographic plates in darkness, no industry was carried on with such feeble illumination as that of coal mining. In the speaker's opinion the dominating factor in the production of miner's nystagmus was the low illumination found both in the open light and in the coal mine safety lamp. It was quite justly alleged that many accidents were due to carelessness on the part of the workmen, but might not increased illumination lessen the incidence of those accidents? If we conserved our manpower by diminishing the incidence of accidents and disease we should necessarily increase the output. The direct result of increased illumination should be increased output.

2. The Clinical Bacteriology of the Pneumostreptococcus Group. D. M. Lewis.
3. Notes on the Use of the Portable Respiration Apparatus. Francis G. Benedict.

1. The Meaning of the Normal.—A. Le Roy Johnson calls attention to the confusion of ideas as to the meaning of the word normal as it is employed in present-day medical and dental literature, and discusses the subject from the dental point of view. The nature of the structures with which the dentist is concerned, *i.e.*, the teeth and their supporting and surrounding tissues, forces him to a careful analysis of the meaning of the normal. The conception of the normal dental arch is the foundation of modern dentistry. To assist in establishing and maintaining the normal functional activity of the masticatory apparatus of the living human being is its purpose. Thus the concept of the normal, what it means, what it signifies, is at the very foundation of dentistry, and its careful analysis is a practical necessity to the progress of the science.

5. Clinical Interpretation of Scarlatinoid Rashes.—Moses Scholtz offers an interpretation of scarlatinoid rashes as the result of a study of their symptomatology, pathology, and pathogenesis. The theoretical justification of this interpretation would be the advancement of the dynamic biological viewpoint over the static, morphological, which is still too much in evidence in dermatology. The practical advantage of its adoption is the simplification of the nosological conception of the scarlatinoid erythemata and the avoidance of an unnecessary and practically impossible differentiation. The advanced views are summarized as follows: 1. Scarlet fever rash is not a well-defined and distinct dermatological entity and cannot be differentiated from the rest of scarlatinoid rashes; it is merely a specific type of toxic scarlatinoid erythemata. 2. Scarlatinoid erythema is not an independent clinical entity, but merely a symptomatic erythema caused by all varieties of systemic toxins. 3. The differentiation of scarlatinoid erythemata cannot be made on purely dermatological grounds, but essentially on the associated clinical symptoms and the mode of development. 4. Nosologically scarlatinoid erythemata should be regarded as an erythematous type of the great generic group of erythema multiforme.

3. Relationship of Ophthalmology to Group Diagnosis.—Homer E. Smith defines the oculist as "the clinician raised to the *nth* power, who, in addition, is 'one skilled in diseases of the eye'." Specialism, he holds, when by this is meant the treatment of a single organ of the body, is manifestly an absurdity and an impossibility. In ophthalmology not even one of its four grand divisions, the external and internal diseases, refraction work or surgery, can be so isolated as to come within the scope of the lexicographer's definition. The external diseases of the eye may be segregated as conjunctival, scleral or corneal, but the oculist may need the bacteriologist, the hematologist, the serologist, or the microscopist to make the diagnosis complete or to indicate the proper line of treatment. The ophthalmoscope will reveal abnormalities of the media or fundus but to correlate these to their proper etiological relationship might mean a search through every organ of the body and perhaps a chemical or biological examination of every body fluid. The oculist cannot be an expert röntgenologist, but there are times when only the x-ray will solve his problem. The eye grounds may

show beginning disease but as yet not sufficiently advanced to permit of any differentiation as to type, as to whether it is tuberculous, syphilitic, malignant, infectious, toxic, leukemic, or diabetic, or whether it is due to any other of a dozen different systemic disturbances. Here the oculist is in need of group diagnosis. Even the surgical status of the patient may need the help of the internist, and the operability of the eye calls for the aid of the bacteriologist. If one is to cope successfully with ophthalmological problems one must call to one's aid the help of experts in every division of medical research.

9. The Treatment of Eczema. J. S. Eisenstaedt.

1. Acidosis in Nephritis.—Chace and Myers recall the fact that the term acidosis, although originally coined by Naunyn to apply to the ketosis of diabetes, has come to be used in a much broader sense with the development of knowledge of the subject. Obviously, acidosis may result either from an abnormal formation of acid substances or, as in nephritis, from a decreased elimination of normally formed substances. Under conditions of health, the blood is uniformly maintained at a constant slightly alkaline reaction through the influence of the bicarbonate, phosphate and proteins of the blood. The following factors have been suggested as a measure of the degree of acidosis: (1) Lowered carbon dioxide combining power of the blood; (2) lowered alveolar carbon dioxide tension; (3) decreased affinity of hemoglobin for oxygen; (4) reduced alkalinity of the blood; (5) increased hydrogen ion concentration of the blood; (6) increased intensity of urinary acidity (hydrogen ion concentration), and (7) the retention of alkali by the body in cases in which the kidney is capable of rapidly excreting an excess of alkali. All these factors have furnished valuable information in the development of knowledge of the subject, but the first, second, and seventh have yielded information of special clinical value. From their study of the subject the writers hold that all fatal cases of chronic nephritis with marked nitrogen retention show a severe acidosis, sufficient in many instances to be the actual cause of death. In some cases of acute nephritis and acute exacerbation of chronic nephritis the distress is apparently due to the acidosis, since the judicious use of sodium bicarbonate results in general clinical improvement. With the rise in the carbon dioxide combining power of the blood, the dyspnea and hyperpnea disappear.

5. Arterial Hypertension.—Frederick M. Allen discusses the theories regarding the causes of hypertension; the restriction of water and salt; cases of pure hypertension; hypertension with kidney impairment; hypertension with diabetes or severe nephritis; limitations in treatment. Under the last head he mentions certain precautions or limitations with regard to the practical application of the principles outlined. First, a diet which is reasonably satisfying and at the same time sufficiently poor in salt is not so easy to arrange as it may appear. Both physician and patient may believe that strict abstinence from salt has been maintained, when analyses will show the blood chlorides undiminished and an output of from 5 to 10 gm. in the twenty-four-hour urine. Such analyses are important for controlling the treatment, and no pressure is rightly called irreducible unless the daily chloride excretion has been reduced to practically zero. Second, some quantity of salt is considered indispensable in the permanent ration. This is stated as about 2 gm. for normal persons, but the limits for nephritics have never been determined. On the one hand, it is not certain that the intake need be as great when the output is obstructed. On the other hand, there may be danger in withdrawing salt from certain nephritics, especially with nitrogen retention, who seem to need much more than 2 gm. of salt for its diuretic action to ward off uremia. As a rule the outstanding effect of undue salt privation has been weakness. It is necessary, therefore, to work out salt rations for individual nephritics which may range from almost zero to a considerable quantity. Third, restriction of salt or fluid, like every dietetic treatment of organic disease, is only palliative. Success is not uniform as in the treatment of diabetes, and complete or partial failures are more or less numerous. When the first results are more or less satisfactory, there is still reason to fear that the same patients may pass into a hopeless condition in the course of months or years. Furthermore, the most effectual relief of the hypertension demonstrates strongly that the essential trouble is more than mechanical. Reduction of the blood pressure nearly or completely to normal may still leave the patient an invalid, either from weakness due to the strict salt privation which is necessary to hold down the pressure, or still worse, if salt is given so as to allow the pressure to go up. They may also be subject to attacks of hypertension and accompanying symptoms from little or no evident cause. Notwithstanding these limitations, the benefit of suitable chloride restriction for hypertension is still great, in making patients more comfortable, diminishing the danger of apoplexy, and possibly also in actually checking the progressiveness of the disorder.

The Lancet.

February 14, 1920, cxcviii, 7.

1. Hunterian Oration on Blood Vessels and Pressure. Leonard Hill.
2. The Results of Protective Inoculation against Influenza in the Army at Home, 1918-19. Major-General Sir William Leishman.

4. The Periodicity of Influenza. C. O. Stallybrass.
5. An Efficient and Economical Pylon. W. Montgomery Johnston.

3. Complement-Fixation Experiments in Influenza.—Fry and Lundie report a continuation and amplification of studies previously published (*Lancet*, 1919, ii, 51) concerning an organism isolated from cases of influenza. The serum of the patient from whose blood this organism had been isolated had shown definite complement-fixation with an antigen prepared from the organism. This result encouraged the writers to experiment with sera obtained from other cases of influenza, which had been investigated during the two previous waves of the epidemic. Syphilitic and other patients were used as controls. The experiments grouped themselves under the following heads: 1. Old sera obtained from cases of influenza at the height of the epidemic in 1918-19. 2. Fresh sera and cerebrospinal fluids from recent cases of influenza. 3. Control sera (*a*) from normal individuals; (*b*) from syphilitic patients who have never had influenza; (c) from patients with no recent history of influenza, and (*d*) sera from patients suffering from other pyrexial diseases, typhoid fever, malaria, tuberculosis, etc. The total number of influenza sera examined is 15, which includes five old sera, eight fresh sera, and two influenza cerebrospinal fluids. The observations are summarized as follows: 1. An antigen prepared from an organism isolated in the third wave of the epidemic shows fixation of complement with sera derived from cases of influenza, both recent and those occurring in the previous waves of the epidemic. 2. This complement-fixation is absent in the case of sera from normal individuals who have never had influenza. 3. It is absent in the case of sera from individuals who are suffering from other specific diseases, and are free from any recent history of influenza. 4. An antigen which has been prepared from another microorganism will show no fixation of complement with sera from cases of influenza.

7. A Method of Treating Tinea. C. J. Glasson.

4. Observations on the X-Ray Treatment of Neoplasms.—G. E. Vilvandré gives the result of observations of facts and deductions which have been forced upon him during the past three years, the object of his investigation being not only to obtain successes, but to inquire why success was achieved in some cases and failure in others. Looking back over the cases of new growths treated by *x*-rays in the *X*-ray Department of the London Hospital, he found the greatest benefit or inhibition in sarcomatous neoplasms, and in the slow-growing varieties. Leaving rodent ulcers on one side—in which radium treatment shows at its best—it may be said of carcinomas that the results of radiation are not striking. Vascularity was not the determining factor, since experience with enlarged spleens—it is difficult to imagine a more vascular organ—showed that under *x*-rays the diminution of enormous spleens, such as are seen in leukemia, is most striking. Breaking down malignant glands such as follow "epithelioma" of the lip, or squamous-cell carcinoma springing upon an ulcerated lupus lesion, do not do well under *x*-ray treatment. Neoplasms of the lung react to hard rays, but heavy filtered doses are necessary. Bulk is no hindrance; it is the nature of the growth that counts.

5. Chronic Infection of the Faucial and Post-Nasal Lymphoid Tissue in Children.—Percival W. Leathart calls attention to the fact that a child with enlarged tonsils and adenoids is not ill because of the increased size, but because of a chronic infection of its faucial and post-nasal lymphoid tissue, which serves not only as a nidus for the manufacture of toxins, but also as a port of entry for many other systemic diseases. This condition of chronic infection, which is extremely common, is easy to diagnose if the three cardinal physical signs—enlarged tonsils, rhinitis, and enlarged cervical glands—are kept in mind. Running ears, bronchitis, mastoiditis, etc., are physical signs to be noted, more correctly described as complications. The disease is highly infectious, as shown by the facts: (1) That it is far more frequent among school children than among children who do not go to school; (2) that when one child in a family is attacked the disease subsequently spreads to others who were previously healthy; (3) microorganisms can always be grown from the nasal and post-nasal secretions, which are normally sterile. There is a tendency to chronicity, the child, in such case, being a "carrier," and consequently a source of danger to all healthy children with whom he comes in contact. The direct complications are far reaching, spreading beyond the sphere of the throat and ear surgeon, the ophthalmic surgeon, and the laryngologist, into the domain of the physician in the way of bronchial affections, and broncho-pneumonia. The indirect complications are even more serious, for the lymphoid tissue, having lost its natural resistance, is rendered more liable to become a port of entry for other specific infections, such as tubercle, rheumatic fever, measles, scarlet fever, diphtheria, and influenza. Treatment includes prevention and the treatment of the individual. If the latter is satisfactory, complete removal is necessary.

Hygiea.

January 16, 1920, lxxxii, 1.

Embolus in the Femoral Artery Removed by Operation.—Sundberg relates the case of a man of 63 with chronic myocarditis and atherosclerosis who suffered with an embolus in the femoral artery. Twelve hours after the earliest symptoms the author cut down on the vessel and succeeded in extracting the embolus intact through the incision. The arteriotomy wound was then closed with button sutures, which were so applied as to spare the intima. Healing of the vessel was perfect. The removed embolus was 86 cm. in length. The patient made a complete recovery and has since remained well. In literature the author has been able to find twenty such cases, not counting emboli in the pulmonary artery. The total number of permanent recoveries is six, and of these no less than four were at the hands of Swedish surgeons—Key, Bauer, Lundmark, and the author. Bauer's patient had an embolus in the abdominal aorta, but the others were in the extremities—femoral twice and brachial once.

Formic Acid as a Remedy.—Kjerrulf first refers to the ancient *aqua magnanimitatis* which contained an extract of ants. In 1822 Berzelius first prepared formic acid in the laboratory, and soon after it was introduced into medical practice, although it had become quite obsolete in the latter half of the nineteenth century. But of late years there has been a slight tendency to make use of formic acid and formates in cardiac disease. This is an odd coincidence, for the old *aqua magnanimitatis* received its name from its supposed power to exalt the courage. For that purpose a half tablespoonful was given in wine just before the ordeal. The formula of the *aqua* called for 2 pounds of ants, 3 pounds of alcohol, and about 100 grams of spices, the mixture being distilled. Just as the textbooks had almost ceased to mention formic acid at all Huchard announced that it possessed toni-muscular and diuretic properties which rendered it applicable to cardiac diseases. But a German, Krull, had announced as far back as 1901 that the acid had some virtues in psoriasis and gout, and this author seems to have taught its virtues over a period of twenty years—from 1891 to 1911—giving it in minute doses. In 1909 Merck was making it as a drug in use, and in 1905 Couch, in the MEDICAL RECORD, recommended injecting the remedy for rheumatism. Another American, Stern, had used it for sixteen years in the same and other chronic affections.

American Trypanosomiasis in Venezuela.—The *Anales de la Dirección de Sanidad Nacional* of Caracas, which is in its first year of publication (January-June, 1919, i, 1-2) contains an article by Tejera on the transmission of Chagas's Disease in Venezuela. Until recently the latter was believed to be limited to certain parts of Brazil. In the latter country the transmission is effected almost entirely by the *Conorrhinus megistus*, and the incidence of the disease is determined by the incidence of this insect. The latter is closely related to the "big bedbug" of our Southern states, and the "kissing bug" of the newspapers. It was originally believed that the species in all these insects is identical, but it has since appeared that several closely related species are concerned. The disease is said to be known in the Western states of the republic as "Pito bite." Not until 1918 was it discovered that the transmitting insect of the latter is the *Rhodnius prolixus*, closely related to the *Conorrhini* above mentioned. It is not the sole agency, for another *Reduvius*, as yet unclassified, has been found infected. This may not mean that it is a human blood sucker, for it may prey only on certain species of animals. Officially the *Conorrhinus megistus* does not exist in Venezuela. The *Rhodnius* is well known in the Western states by a number of popular titles, varying with the locality, as the "whistle," the "sucker," the "bush-bug," etc. It can readily be infected with the trypanosome through allowing it to bite guinea pigs previously infected, and can then as readily convey the disease. A number of human patients have been studied and the affection is believed to be not uncommon. Chagas's disease is now well known to medical men, and clinically is at first an acute thyroiditis. Recent studies in Brazil have made it probable that a variety of blood-sucking insects, which includes the ordinary bed-bug, are capable of occasionally transmitting the disease. The *Conorrhinus Laporte* of Venezuela, which has been known since 1832, is theoretically capable of transmitting the disease by reason of its habits and preferences, which are those of blood sucking hemiptera in general.

Society Reports.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

Annual Meeting of the Eastern Section, Held at Newark, N. J., February 7, 1920.

Dr. Wells P. Eagleton in the Chair.

A New Form of Medication for the Nose and Nasopharynx.—Dr. Wolff Freudenthal of New York City made this preliminary report. The author stated that not all cases of dryness in the nose and throat, headache, etc., are relieved by operative measures. Nasal douches, salves, etc., are not always effectual. This was because the parts affected were often not reached by the medication. Thus the author had sought means to apply some form of medication that would remain in contact with the affected parts. Freudenthal tried a nasal bougie, which was found unsatisfactory on account of displacement. Then a simple apparatus was constructed consisting practically of nothing but a few wires fastened together. This served to hold the bougie in contact with the part desired. The applications could be made easily in the office without cocaine, although in sensitive people a few drops of a 1 per cent. solution of cocaine had been used. The patient could be shown how to apply the bougie himself, at his home. So far the author had used chiefly bougies of cocoa butter containing boric acid. Other ingredients used had been tannic acid, eucalyptol, and adrenalin, the latter in one case of perennial vasomotor rhinitis, with great success. Usually from 3 to 8 minutes were reqired to dissolve a bougie. A pledget of cotton in the nose prevented flowing away of the dissolved portion. In some cases the bougie was not dissolved. Such cases presented absolute atrophy of the mucous membrane. The time of dissolution of the bougie would act as a measure for the function of the nasal mucous membrane. It was found, also, that in cases of sinus affection the alterations extended sooner or later to the nasal cavity itself. The bougie treatment, it was stated, was an adjunct to, not a substitute for, office treatment by the physician himself. In view of the rapid absorption of drugs by the mucous membrane of the nose, it was suggested that careful experimentation be made as to the therapeutic value of drug administration by this means.

Dr. N. Wilson of Elizabeth, N. J., said he would like to ask the speaker how long he kept this apparatus in the nose. Had he made any experiments as to the melting of the bougie at a temperature of 98° outside of the body? Whether the mucous membrane was functioning or not was not so important as the temperature of the bougie. At body temperature in the office this would be dissolved.

Dr. T. J. Harris of New York said he always welcomed every paper from Dr. Freudenthal. It was bound to be worth while and helpful. It was very refreshing to see a paper which was off the beaten track. In recent years the society had been so absorbed in surgical questions that it had more or less lost sight of medication. Dr. Freudenthal made the remark that we failed to get 100 per cent. good results from surgery. Therapy was often insufficient, and results were by no means 100 per cent. Other factors and elements entered into the cure which Dr. Freudenthal had touched upon. The question of the destruction of the mucosa was a very broad one. What Dr. Freudenthal had said in regard to the impossibility of any form of medication being able to restore a hopelessly diseased gland to normal function was also true. In regard to the bougie, he would have been glad had the speaker touched not merely on the introduction of the bougie but also on the results obtained. It seemed that in the long run it had worked out well. It was also important for specialists not to lose sight of the fact that there was other than local treatment in nasal disease. He felt more and more impressed with the beneficial results from the treatment of the nose and sinuses by dieting. Great benefit was obtained by treatment of the gastrointestinal tract, or any other tract of the body where there was good reason to suspect disturbance. More attention should be given to this line of therapy, and careful investigation should be made of any and every possible channel of infection or of reflex irritation which might aggravate or help to maintain irritation of the nasal mucous membrane. This was particularly true of the gastrointestinal canal.

Dr. W. P. Eagleton of Newark said that Dr. Freudenthal spoke of the value of medication in systemic disease. That point had been greatly neglected. When one considered the tremendous influence of cocaine and adrenalin, it seemed inconceivable why it had not been tried by this means. There must be many occasions when administration of stimulation by this channel could be made. Stimulants could be rapidly absorbed and in the absence of hypodermic medication, it would be valuable.

Dr. Freudenthal, in closing, said he had learned a great deal during this interesting discussion. Dr. Wilson's remark was important. Heat alone would dissolve bougies at a temperature of 98°, but the temperature of the interior of the nose was not 98°. To dissolve the bougie in the nose it needed more than heat; it took moisture, too. He was sure that he appreciated the remark that one did not get 100 per cent. results. Operation would remove certain troubles, but it would not cure everything. Men should cease to operate as much as they had been doing during the last few years. Without general treatment one would never get the full results. In regard to temperature, one must bear in mind the climate in which he lived, and also that many of us were office workers. With an office temperature of 80° and a moisture of 15 per cent., instead of the normal amount, it was no wonder that the nasal mucosa dried out.

Report of Two Cases of Cerebellar Abscess.—Dr. C. J. Imperatori of New York made this presentation. He said that the diagnosis of otitic cerebellar abscess before operation was made with great difficulty, although possible in some cases. Two cases were cited: one a Pole, 32 years of age, occupation stableman. This man had had a chronic discharge from the right ear for eight years, and for a few weeks prior to being admitted to Bellevue Hospital complained of dizziness and falling to the right, and some mornings vomiting. He was deaf on the right side. Tests showed facial paralysis, loss of cochlear and static function, and radiographs showed a mastoid sclerosis. The possibility of cerebellar abscess was considered. This was found at operation and two drams of foul-smelling pus evacuated. The patient was discharged cured in two months. The condition was cerebellar abscess complicating labyrinthine suppuration. The second patient, a Greek, aged 42, was admitted in a stuporous condition. He lay on his left side, with limbs flexed. The spinal fluid was under pressure—225 cells. Radiographs showed a sclerosed mastoid on the left side. A radical mastoid operation was done. The patient's condition did not improve and in 36 hours an opening was made over the cerebellum, posterior to the sinus; no pus was found. Another opening was made anterior to the sinus and a half ounce of foul pus was evacuated. The man died 12 hours after operation. In these cases it would seem justifiable to do radical mastoidectomy, labyrinthectomy followed by exploration of the cerebellum.

Dr. W. P. Eagleton of Newark said there were many points about these two cases which threw light on a very difficult subject. Knowledge of cerebellar abscess was more or less in the experimental stage. Cerebellar abscess was frequently a complication of labyrinthitis. We should understand the problem and the necessity of attacking the principal lesion first. Any communication that gave in detail the findings in cerebellar abscess, detected at operation, was most valuable. In looking over the literature of the cases reported, in 127 a post-mortem had been obtained, but very few reports of these cases were of scientific value. The men who reported them made no attempt to systematize the examination of their cases, or to make a careful record, symptom by symptom. The result was that the whole subject remained in a state of chaos. Details of the neurological examination were often entirely lacking. Of the whole 127 cases, in less than 12 had a detailed report been made. There were a

few specially interesting points in regard to the value of certain signs to which enough attention had not been paid. One of these is the value of a "protective meningitis" as a diagnostic symptom. He had coined the word "protective meningitis," instead of "sympathetic meningitis." Its value in the diagnosis of an intracranial lesion had been of great importance. With a high cell count this should always be suspected. The lesion was then beyond the labyrinth. The brain lesion itself should then be attacked. Another point to remember was that with suppurating ear, with suspected brain abscess, in the upright position one failed to get a reaction from the vertical canals, which did not functionate. With the body lying back the horizontal canals would functionate. The cold caloric did not react on the affected side. In these cases one should be induced to open the dura instead of opening the labyrinth. One point was essential—ligation of the sinus prior to operation. This removed the technical difficulties of the operation, leaving a very large field that could be kept clean. This method would very soon be adopted as a universal procedure.

Dr. W. C. Bowers of New York City said that several years ago he saw a case with a cell count of 2600. There was marked rigidity and a marked Kernig. The child had abscess under pressure, posterior to the sinus and external to the dura. A spinal puncture was done. In two weeks the child got well. There was considerable increase in the cell count, but no intracranial pathology.

Dr. E. P. Fowler of New York said that in regard to the increased cell count in cerebellar abscess, he would like to mention a recent case in New York which recovered following labyrinthectomy. The case was a very chronic one. There had been meningitis and labyrinthitis. There was a recurrence after one and a half months and the patient was brought to the Manhattan Hospital and there operated upon. There was no abscess except an ordinary mastoid. He would like to know the value of past pointing as a sign.

Dr. T. J. Harris of New York asked to know the present conclusions in relation to past pointing. What was the chairman's opinion?

Dr. L. M. Hubby of New York said that one thing about past pointing was useful to know. When nystagmus was present, if one turned the patient over on the diseased side and had him turn the eyes as far as possible, one could often increase past pointing.

Dr. W. P. Eagleton of Newark said that there was a modification, but he did not know how far this was diagnostic in cerebellar abscess. These cases were often not examined when it was possible to examine them; one could not examine a patient in regard to past pointing when he was in a comatose condition. There was a long time previous to this when records could have been made. However, these were not available. There was no effect on past pointing in slow-growing tumors. Most of these patients showed an outward deviation, but whether this was also true in cerebellar abscess he could not say.

Dr. J. W. Park of Harrisburg, Pa., asked whether the doctor said that there was a careful ophthalmoscopical examination made or not. He thought that in cerebellar or meningeal conditions this should be done, even as often as four hours apart, with careful notation of the condition of the central arteries and veins.

Dr. W. C. Bowers of New York said he had a case of cerebellar abscess a month ago. The man had had the condition for a year. He had been operated on for a mastoid condition, and had had a radical operation. He returned with increased symptoms and complained of headache and tendency to fall to the right. There was nystagmus and falling to the right and forward; no past pointing. This was normal on stimulation of the right canals in every direction. He was totally deaf. At operation it was found that the bone was destroyed over the posterior and middle fossæ. Even the bone in the angle between the two fossæ was destroyed and the facial nerve was completely exposed. The necrotic bone had to be removed. The dura was very thick in all parts. It was impossible to find any trace of the sinus. When he came back he still had the former symptoms and optic neuritis as well. There was no spontaneous past pointing. When exploration was made he endeavored to ligate the sinus and went to the front of where the sinus should be and found a thick-walled cavity. He attempted to pass ligatures, but it was hard and dense. It was thought that the case was one of sinus thrombosis, and on cutting through it was found that this was true. The sinus thrombosis probably caused the abscess, rather than the labyrinth wall, which was one-half inch thick. Three-quarters of an inch was cut away, leaving a large opening. Two weeks ago he was doing very nicely. There was no past pointing in that case.

Dr. C. J. Imperatori said that a very careful opthalmoscopic examination was made, and was considered in the diagnosis. The eye grounds were negative, according to the report of the eye men. There was no possibility of past pointing; the man was comatose, and except that adiadochocinesia was brought out he could do nothing. He kept on doing that and kept it up. In the first case there was a slight spontaneous past pointing on the left. The lesion was on the right side. It would appear that without a high cell count the prognosis would be more favorable. He was not able to explain why the horizontal canals would functionate on the sound side and the vertical canals would not.

Abscess of the Frontal Lobe, Simulating Frontal Sinusitis.—Dr. S. McCullagh of New York presented this topic. The patient, a girl of 11, was admitted to the Manhattan Eye, Ear and Throat Hospital with headache, somnolence, and swelling of the left upper eyelid. Seven years previously she had fallen 40 feet and suffered compound comminuted fracture of the skull. Mentality had been low ever since. On admission the patient was lethargic and resented being roused. The left eyelid was ptosed. There was marked tenderness over the frontal sinus. After some days, as the condition did not improve, operation was decided on and the frontal sinus was opened. Free pus and granulation were found. The incision was deepened and the frontal lobe explored. About an ounce of thick, greenish pus gushed out. The walls of the cavity were thick and did not collapse. The wound was gently irrigated and a rubber drainage tube put in. Culture from the brain abscess was sterile. The child was extremely uncontrollable, and repeatedly forced out the drainage tube with screaming and struggling. The wound, however, healed promptly. It was apparent that this abscess must have occurred at the time of the cranial injury and had laid dormant for years. Subsequent reports from school showed that the child's demeanor was better, but the mentality had not improved.

Dr. W. Freudenthal of New York asked what was the condition of the frontal sinus when opened. How did the mucosa appear? How was the swelling of the left eyelid afterwards? Was there edematous infiltration or only pus?

Dr. T. J. Harris of New York said that Dr. McCullagh was to be congratulated upon the satisfactory result of his case, in spite of the difficulties encountered. In many of these cases the diagnosis was made only at the time of operation on the frontal sinus. The headache and high temperature were ascribed to infection of the sinus. One point to be noted in this case was the persistent vomiting. The infection lay in the posterior wall in the majority of cases. The condition was by no means a light one. There were many cases that resulted badly even after operation. Surgery, delayed until the proper time, was distinctly indicated, and Dr. McCullagh's procedure was to be recommended. In the case of one boy, who became comatose after weeks in which the condition was unrecognized, with marked depression of the pulse rate, down to 40 or 50, the patient responded very promptly to operative procedure. In a few days he was mentally alert. A defect in the canal was discovered. In some cases infection was through the lymphatics and blood supply. It was interesting to hear of the prompt recovery of the child, in spite of the difficulty in keeping the dressings in place.

Dr. J. P. Berens of New York said he would congratulate Dr. McCullágh on his surgical results, as proved by the rapid convalescence of the patient. He recalled the case Dr. Harris referred to. The patient made a complete recovery. The frontal sinus was

drained with horse hair, more horse hairs being added until the drain was large enough. The only symptom was a great deal of frontal headache before the operation, and a very slight redness of the eyelid on the left side. The man worked in a bank, and so few were the symptoms that the manager of his bank never knew that he had a brain abscess; in fact, the patient himself did not know that he had.

Dr. H. S. HEDGES of Charlottesville, Va., recalled a case of a boy with extensive empyema of the frontal sinus. The child was doing well ,and was almost ready to go home when he became comatose and died in a few hours.

Dr. J. H. CULP of Harrisburg, Pa., mentioned a case of a man who was injured by an exploding emery wheel and suffered fracture of the frontal and occipital bones. Dr. Culp had removed the loose pieces of bone from the cranium. The man did well for a month, and then developed somnolence and pain in the head, although his mental condition was not impaired. There was a bulging of the sinus and it was decided to open it. At operation an abscess was found in the cavity of the left frontal sinus. The point to be emphasized was that until the time of death there was no clouding of the mental faculties.

Dr. S. M. COATES of Philadelphia said he had a case seventeen years ago in which there was an abscess of the left frontal lobe. The patient had suffered from sinusitis and a left ethmoid involvement. He came back to the hospital later, suffering from brain abscess. The hard capsule of the old abscess in the frontal lobe was found at autopsy.

Dr. W. P. EAGLETON of Newark said that very few cases showed an optic neuritis. The frontal lobe did not interfere with the cerebrospinal circulation. There must be interference to cause increased intracranial pressure. The examination of the eyes every four hours was important. In sinus thrombosis there was a fullness of the veins on one side. Bilateral enlargement was not important. Some years ago it was pointed out that in a frontal lobe tumor there is an optic neuritis on both sides and then development of atrophy on the side of the tumor. That did not apply to frontal lobe abscess. With extradural abscess and frontal sinusitis it was better to explore the frontal lobe. For some reason or other intracranial abscess was much more commonly associated with extradural abscess than with abscess behind the ear. A diseased frontal bone had something to do with disturbed circulation. Osteomyelitis was comparatively common with frontal bone conditions, and almost unknown with temporosphenoidal lesions.

Dr. MCCULLAGH said that the case reported differed from frontal lobe cases following frontal sinusitis. The child's accident was sustained at four years of age, before the frontal sinus had developed. The abscess was formed at the time of the accident, and was dormant for six or seven years. Pus from both the abscess and the sinus were sterile, which would indicate that this was the case. The abscess ruptured through the posterior wall of the sinus and discharged into the sinus. It was a frontal lobe condition. What Dr. Eagleton had said in regard to the blood supply of the frontal sinus from the dura would furnish an explanation as to why this abscess occurred and ruptured through the bony wall. A very slight increase of pressure might cut off the blood supply and then necrosis would result. In this child's case it was difficult to gauge with accuracy the intensity of the symptoms, because the child was so undisciplined and uncontrolled. Reneated fundus examination was negative for any gross lesion. If there was any change in the size of the vessels it was not reported. In answer to Dr. Freudenthal, there was nothing but edema of the eyelid, which changed from day to day. At the time of operation the edema decreased. The mucous membrane lining of the sinus was thick and degenerated. It must be remembered that this abscess did not follow frontal sinusitis at all. It ruptured into the frontal sinus.

Greetings to Dr. Holbrooke Curtis.—Dr. T. J. HARRIS offered a motion that greetings should be sent from the section to Dr. Holbrooke Curtis, who was severely ill. This was in recognition of the fact that for many years Dr. Curtis had been one of the most active and interested members of the society. This motion was seconded and unanimously carried.

A Method of Restoring Tubal Function.—Dr. E. P. FOWLER of New York presented this paper. The speaker said he had obtained very satisfactory results for a long time by the balloon method. The application was well known. The head was turned over to one side and the muscles pulled upon. In normal cases the ears were opened more readily. In obstructed cases it helped the opening of the tube. There had been much controversy as to whether there was any increase of the air of the nasopharynx in swallowing. The catheter did not give an index of air in the nasopharynx during the act of deglutition. Respiration through the mouth, it was said, caused no increase in intranasal pressure, but in ordinary mouth respiration there was some appreciable change in the density of the air in the nasopharynx. There was a perceptible difference in the balloon during ordinary swallowing. He had had patients for ten or fifteen years, with blocked tubes, who had gotten good results from the use of this very simple means.

Dr. G. EMERSON of Orange, N. J., said that the so-called catarrhal otitic conditions were consequences of the systemic condition of the patient. These cases were familial.

Dr. T. J. HARRIS of New York said he would like to go further than Dr. Fowler. For a long time he had maintained that persistent and often unwise treatment of the middle ear was harmful. Any treatment by inflation without getting at the cause was harmful. One could not cure these cases without getting at the local infection, which was mostly in the nose. The condition would progress unless one could clear up the infection.

Dr. E. L. VANSANT of Philadelphia said that not enough attention was paid to the anatomical construction of the tube. The tube was lined with ciliated epithelium. This must be restored before one could keep the tube clear of mucus. A very simple method was the use of warm air in the Eustachian tube.

Dr. T. CORWIN of Newark said he would like to call attention to conditions of the bony structure and their imperfect development associated with catarrhal conditions. A number of years ago radical suggestions were made, namely, that nasal respiration would be improved by direct mechanical expansion. The maxilla was to be expanded by pressure exerted through the teeth. It had been shown, and advocated by many men, that in early life when the second teeth were about to erupt, expansion of the jaws could be accomplished without any uncomfortable pressure. The jaws were then in a plastic condition. After puberty it became tedious and difficult. A contracted hard palate, or defective palatal development, was evidence of faulty development of the upper maxillary bone. This, in turn, was associated with catarrhal conditions.

Dr. H. S. HEDGES of Charlottesville, Va., asked the speaker to explain the mechanism of the muscles. He had said that they tended to open the tube when the head was on one side, but it seemed that the tensor palati and levator palati remained the same while the palatopharyngeus was more relaxed.

Dr. W. H. HASKIN of New York said that Dr. Brown of Washington was a great advocate of rapid expansion, and he did not hesitate to do a real surgical operation. He did not merely put on the brace. He made an incision and put the chisel between the maxillæ and held the maxilla open. This was widened by a plate until the tissues closed in.

Dr. FOWLER, in closing, said that the whole trouble with regard to inheritance was that "some do and some don't." If there were anything in the theory it should be more regular. In regard to the catheter, he agreed with Dr. Harris absolutely, but there were many patients who, either from lack of time or from lack of money, found it impossible to come with sufficient frequency. That meant that they must do something to help themselves. In these cases the apparatus had helped a great deal. He thought the whole subject of focal infections had been overdone. During the war they often would have lost every tooth in the regiment. He had to call on the colonel to stop it. These teeth were no doubt diseased, but they sufficed to chew with during the war, and served their purpose. In

regard to the ciliated epithelium, it was impossible to inflate without some trauma, but one had to choose the lesser of two evils. One had to get an opening somehow. In regard to expansion of the jaws, it was being overdone. Blocking was nearly always due to congestion, and the absolute blockage was not as much as one thought. Wire apparatus was efficacious, but disagreeable to wear. In regard to the mechanism of the muscles, the pharyngoscope showed that the pharyngeoglossal and the styloglossal were stretched with their fasciæ and aponeuroses. They exerted more or less of a pull.

Deep Cervical Abscess and Thrombosis of the Internal Jugular Vein.—Dr. HARRIS P. MOSHER of Boston read this paper. Examples of cases were cited in which, had the proper diagnosis been made, a fatal termination could have been avoided. The speaker said that the vital structure in the neck, as regards infection, was the internal jugular vein, especially in deep cervical abscess. Chills and septic temperature occurred with phlebitis or thrombosis of the vein. The vein should be laid bare and its condition determined. In phlebitis the vein should be tied, in thrombosis, dissected out. A deep servical abscess should be regarded always as a perijugular abscess. It should be dealt with as a perisinus abscess and watched knife in hand. In the past the cases had been labelled septicemia, and surgery was confined to taking blood cultures. This often led to fatal results. Sinus thrombosis had long been recognized, but the same condition in the vein lower down had escaped notice. Infection came as readily from the tonsil as from the middle ear, and this was one more example of the obvious thing being the hardest to see.

Dr. W. FREUDENTHAL of New York referred to two cases belonging to this class. One, a middle-aged man, had been operated on for mastoid trouble two or three weeks before, and he still had pain and swelling in the neck. The second case was that of a young woman, 25 years old. She had a retropharyngeal abscess. The larynx was almost entirely closed. Both arytenoids were swollen. There was an abscess in the arytenoids. An incision was made by the indirect method. One arytenoid was opened a good deal, and pus came out. A tracheotomy was done and she could breathe better. This perhaps had a bearing on this type of case.

Dr. W. W. CARTER of New York said that in listening to this presentation he had just been able to diagnose a case during the last few minutes, although two years after the patient died. The patient was a nurse, 25 years of age. She had suffered from a peritonsillar abscess, which was opened by the surgeon, but still the patient ran a high septic temperature, varying from 106° down to 96°. She was getting worse. This was six days after the peritonsillar abscess had been opened. The surgeon noted induration of the side of the neck, and thought there was deep-seated pus. He made an elaborate incision, but did not discover any pus. He supposed the induration was low down in the carotid sheath. The patient did not get any better. Dr. Carter was asked to see the case and he said he saw the battle for life was nearly over. The patient died after ten hours. There was no autopsy. He regarded the case at the time as one of death from extreme sepsis.

Dr. S. MCCULLAGH of New York reported a case as a matter of differential diagnosis. The patient had an acute catarrhal condition of the right ear, and had had previously an acute suppuration of the left ear. When seen the left ear was normal. The right ear cleared up under treatment. A short time afterwards his adenoids and tonsils were removed. He was a young man, 22 years of age. About a week after the removal of the tonsils he came to the office, complaining of severe earache on the left, with bulging of the drum. A paracentesis was done. Temperature was 101°. He went home and went to bed. Soon after his family telephoned that the patient was screaming with pain in the head. He had a chill and temperature of 106°, with remissions. The left ear drained very nicely, and there was nothing to be seen in it. A day or two after the paracentesis the temperature persisted. At that time, on the left side of the neck, over the site of the tonsil, there was a slight induration of the glands. Blood culture showed the blood swarming with streptococci. The diagnosis was phlebitis of the internal jugular on the right side, following tonsillectomy, and ligation of the jugular on the left side was advised. The lateral sinus was thrombosed; it was blocked off and the jugular excised. The patient made an uninterrupted recovery. In these cases there was also a possibility of the ear condition being overlooked by going into the neck only.

Dr. H. P. HOWELL of New York said he was surprised the author of the paper did not mention Ludwig's angina. It was frequently considered in the hospitals a few years ago.

Dr. W. C. BOWERS of New York said he saw a patient who had a swelling situated over the left side of the neck. He had a high temperature. The dentist was called in and extracted the two last molars. The family doctor then made a small incision in the anterior pillar of the tonsil, thinking there was an abscess. The patient had a temperature of 106° and severe chills. There was a small swelling on the left side of the palate. A larger incision was made and about half a teaspoonful of pus came out. A blood culture was made and *Streptococcus hemolyticus* was found. Five or six days later the temperature was ranging from 99° to 106°. The jaws were then opened under an anesthetic, and a retropharyngeal abscess, containing 3 ounces of pus, was opened. Four hours later the man died. This belonged to the same class of cases. The whole picture was one of sinus thrombosis.

Dr. LEWIS FISHER of Philadelphia said he had a flash similar to that of Dr. Carter, but his patient was alive to-day. He did not recover from a peritonsillar abscess, and he had a chronic suppurative ear at the same time. Phlebitis of the lateral sinus was suspected. The man had had a radical mastoid done, but there was no trouble in the sinus. The temperature was septic, 96° to 107°. The jugular was tied and the following day the patient was practically well. In any similar case, the speaker said, he would ligate the jugular first.

Dr. H. R. MOSHER thanked the members very much for the very full discussion. The point he wished to make was the unifying conception of the deep retropharyngeal abscess. The pharyngeal fossa was one and the same thing as the jugular fossa. Pus sometimes ran down into the trachea and strangled the patient. It was very gratifying to have so many members recall similar cases. Dr. Howell had said that infection could come from the submaxillary gland. It could come from anywhere. As to Dr. Fisher, whatever he did was always right.

Vestibular Tests as an Aid to the Diagnosis of Brain Disease, with Report of Cases.—Dr. LEWIS FISHER of Philadelphia made this presentation. In Case I the patient was 20 years of age, and was admitted complaining of continuous severe headache, vomiting after meals, blurred vision, drowsiness, anorexia. After neurological examination the case was diagnosed as one of right cerebral tumor and temporal decompression was advised. From an otological standpoint the case was one of central lesion, and presented the problem of accurate localization within the cranium. Good past pointing in both arms apparently excluded the cerebellum. Otological tests suggested that the lesion involved the cerebro-ocular pathways of nystagmus, originating on the right side. Autopsy later showed a large subcortical abscess in the right cerebral hemisphere. Case II, a woman of 62, complained of severe buzzing in the left ear, vertigo, and sharp pain across the top of the head. Otological tests produced a vertical nystagmus, instead of horizontal, indicative of a central lesion. A difficult point in the diagnosis was that the left, or vestibulary nonfunctionating side, had practically normal hearing. A selective destruction of the vestibular fibres only appeared unusual. However, a diagnosis of an angle lesion was made. Autopsy showed a tumor of the petrous portion of the left temporal bone encroaching on the cranial cavity, and extending to the antrum of Highmore. The diagnosis of a cerebellopontile-angle lesion was, however, made when the patient's hearing was good on both sides.

In the third case, a young man of 28, the evidence pointed to the lesion being both central and peripheral. At operation a tumor was found in the cerebellopontile angle, and at autopsy, a few days later, another growth was found to the right of the posterior fossa, involving the cerebellar peduncles.

Dr. W. B. EAGLETON of Newark said that this was another instance of the specialists invading the field of general medicine, and adding their quota to the knowledge that belongs to that field.

Dr. J. H. CULP of Harrisburg, Pa., said he would like to ask how it was that the patient of 55 years retained absolutely good hearing on the side where the tumor was found.

Dr. S. A. BRUMM of Philadelphia thought there should be something said to emphasize the use of vestibular tests. It should be imperative for every otologist to do this more than they do. From experience in the army he was astonished to see how little men who called themselves otologists knew. At the present time he would view with skepticism the diagnosis made by a man who did not know the value of, and practise vestibular tests.

Dr. W. P. EAGLETON of Newark said he would like to know the speaker's opinion as to the value of pointing and deafness in induced nystagmus.

Dr. P. W. PARK of Harrisburg, Pa., asked what was the ophthalmoscopic examination; was anything shown?

Dr. FISHER said that the second patient, the woman of 55 years, had her hearing intact when first examined. She was sent by a general practitioner because she had buzzing in the ear. The good hearing did not persist in this case. The woman became deaf three months before death. She had a proliferation of the bone and involvement of the vestibular fibers before the other fibers. This was the only possible explanation of the phenomenon. As to the ophthalmological findings in these cases, the man with tumor had marked choked disks in both eyes. The woman did not have choked disks. In the first case, a girl, the right eye was clear, but the margins were obscured by exudate. There were two good-sized hemorrhages. The posterior fundus was normal. The eye symptoms suggested cerebral neoplasm on the right side. That was the oculist's report. As to Dr. Eagleton's question regarding the significance of past pointing in cerebellar abscess, he had never been convinced that there was anything peculiar in cerebellar abscess as compared with other lesions. The responses were interfered with in some manner, and very often there would be exaggeration of the response irrespective of the type of lesion.

CLINICAL CONGRESS OF THE AMERICAN COLLEGE OF SURGEONS.

Ninth Annual Meeting, Held in New York City, October 20-24, 1919.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 424)

Radiotherapeutic and Other Methods of Treatment of Cancer of the Uterus.—Dr. S. M. D. CLARK of New Orleans spoke informally. He stated that cervical carcinoma might be divided into groups. In the first group were included those cases in which the existence of the carcinoma had made no constitutional inroads; the patient was a good surgical risk; the disease was confined to the cervix, and there was no infiltration or invasion of the uterus; the uterus was freely movable. In this group of cases he favored radical surgery, since it afforded a mortality of only 5 per cent., and in a large percentage of cases, if there were no metastases, a complete cure. After the radical removal of the cervical carcinoma, the stump of the cervix might be cauterized, the abdomen opened and the glands at the external iliac and uterine arteries examined. If they showed metastases they were removed, together with the uterus, and radium was applied. The second group of cases were those which showed, in addition to the local involvement, constitutional impairment, hemorrhage, and a local condition more advanced than in Group 1, there being slight encroachment on the vaginal wall and slight thickening of the parametrium. In this group of cases radiotherapy was a valuable adjunct, but it fell far short of the mark as a curative agent. The application of radium in these cases previous to operation lessened the operative risk 50 per cent. Patients of this group subjected to radium treatment should be operated upon in from four to eight weeks after receiving the radium treatment or else fibrosis would make surgical interference very difficult. Radium was much preferable to the cautery. Radium, as was well known, had a limited penetrating power, and he believed cancer cells could be eradicated through a wider area by operation. This group of cases was the last in which surgery was applicable. The third group comprised the more advanced cases, with uterine involvement, and it was well to leave these cases alone so far as surgery was concerned and to use radium. In these cases radium was received with open arms and marked a distinct step forward. In 19 per cent. of cancer cases the patient died from the local disease and not from metastases, and if the local disease could be controlled the patient's life might be lengthened. In numberless cases radium had brought new life or an extension of life. It relieved symptoms and lessened discomfort in these advanced cases of cancer. Although it was in no way connected with the title on which he was speaking, Dr. Clark said he could not forbear a reference to the early diagnosis of cancer and the prevention of this disease. After a woman had finished the child-bearing period she should be subjected to a physical examination. A lacerated cervix at this time of life provided an inviting soil for carcinoma and should be repaired. There should be a cancer crusade to disseminate information of such facts as that one in every thirteen women who reached the age of 38 years died of cancer. It was the duty of the Congress to keep up pressure and to keep hammering into medical students and at medical societies the necessity for the early recognition of cancer.

Dr. JAMES F. PERCY of Galesburg, Ill., stated that disseminated heat held and would continue to hold a high and successful place in the curative and palliative treatment of all forms of malignancy. The accomplishment of the best results was being temporarily held in abeyance because of a misunderstanding of the correct application of this agent and its use by the inexperienced who would be its friends but who had not learned the limits of its application. It was a valuable remedy because nerve structures, blood vessels, and muscle cells were more resistant to heat than cancer cells. The application of heat through abdominal incisions could be so regulated that the ureters and important blood vessels could be preserved while the cancer cells in the parametrium and lymph channels were destroyed with their load of infection. By the use of heat one did not transplant cancer cells as one did with the scalpel. With the abdomen open the operator could tell when he had applied enough heat and if he gave too much he would know at once and could take means to repair the damage. After treatment with heat the glands could be removed easily but this was not necessary as they would disappear spontaneously. The methods of producing heat had been much improved and there were electrical devices that did more than spread heat; they made heat. The various forms of electric energy devitalized nerves and affected the blood supply, sometimes causing chronic endarteritis. Nature was not prepared to repair these injuries but burns were a part of Nature and she stimulated their repair. The application of heat was something more than a mere local cooking procedure. It was unfortunate that they continued to talk about the cautery as though it were something else than heat; it was essentially heat. Their 1917 record showed 15 per cent. of the utterly hopeless type of cancers cured for periods ranging from 2½ to 5 years on the basis of sixty-five cases. No doubt a review of these cases to-day would show that more could be added to this 15 per cent. Thus far the application of heat had done more than anything else in cancer of the cervix at the time that it was reaching the inoperable stage.

Dr. HENRY K. PANCOAST of Philadelphia said that, in the treatment of malignant conditions by the *x*-ray or radium, one must consider the local growth, the

metastases existing, and the metastases that were likely to occur. Unless all three zones were treated they could not be successful, and they could not be successful unless the primary growth could be removed. In the treatment of carcinoma of the uterus with the *x*-ray, one must consider the possibility of starting up metastases, and the more nearly inoperable a cancer was the more likely was one to start up metastases. The *x*-ray treatment of carcinoma of the uterus could not be considered as strikingly rational. Its purpose was as a supplement to radium and operation. It could be employed as a postoperative aid but he did not believe it was successful unless radium was used as a free operative or postoperative treatment, but he believed it was an advantage to use it with radium. The use of radium was the method of choice in those cases which started in the cervix and than invaded adjoining structures. If the growth had invaded the broad ligaments and the pelvic lymph nodes, radium alone could not cure, but only gave relief from pain and symptoms. Some believed they became worse after radium treatment. The dose of radium should be the maximum one because it penetrated over an area only a few centimeters in diameter, and beyond this area it did no good. One should not depend on radium treatment if cancer was located where it could be removed. The details in reference to radium treatment should be studied statistically. The radium treatment should be given through many ports of entry (ten or a dozen were not enough), and the *x*-ray should be given anteriorly, posteriorly, and in every direction. Such treatment exerted an effect on the intestinal tract, but this was not to be considered in comparison, with the harm resulting from the growth. The treatment with the *x*-ray must be carried out by as uniform a technique as that connected with the use of radium.

Dr. HOWARD C. BAILEY of New York said that in order to form an estimate of the value of radium in the treatment of uterine cancer, consideration must be given to the way it was used. The cases fell into three groups; (1) Operable, (2) Borderline, (3) Inoperable. In the first group radium might be given from two to six weeks before operation and postoperatively as a prophylactic against recurrence. The minimum dose was 2,000 milligram hours. The postoperative dose should be given three or four days after the operation when the patient had recovered her equilibrium. If large amounts of radium were available a dose of 1500 milligram hours might be given in the body of the uterus, the mass of radium being suitably filtered and directed to the fundus of the uterus. Radium emanations should be directed to the parametrium through the vault of the vagina following hysterectomy. Not infrequently so much of the vaginal wall was removed at operation that it was not possible for radium emanations to reach the parametrium through the vault of the vagina. There were two obstacles to the application of radium postoperatively—the thickening of the scar tissue and restriction of the rectum. In certain borderline cases it might be better not to operate but to employ radium treatment and keep the patients under observation. In large cauliflower growths filling the vault of the vagina and certain other large growths, preliminary cauterization, and the application of radium emanation tubes might be employed, but it must be remembered that by just that much time was the treatment of the parametrium delayed. The operability of carcinoma of the body of the uterus was so difficult to estimate that following operation no case received proper treatment without thorough radiation of the pelvis.

Dr. BURNHAM of Baltimore stated that cancer of the uterus and closely allied cancers of the cervix and vaginal vault presented, not one, but a series of distinctly different problems. The treatment depended upon the extent, location, and histological character of the cancer. The prognosis depended upon the operability of the cancer and the technique employed in its removal. Hysterectomy for carcinoma of the uterus had been fully developed and widely employed for ten years; the tendency was to employ it in too advanced cases. In such cases it was only palliative as it relieved the discharge and pain and prolonged life. With the aid of radium many more cases of carcinoma of the uterus were saved. The speaker discussed separately carcinoma of the body of the uterus, carcinoma of the cervix, and carcinoma of the vagina. Carcinoma of the body of the uterus should be treated surgically and not with radium. When operation was contraindicated radium should be used by intrauterine application; its use had been of much help but he had not seen a single case of huge carcinoma of the body of the uterus permanently cured in this way. In advanced carcinoma of the cervix he had seen some marked improvement under radium treatment and in a few cases a clinical cure. He urgently recommended radium in the treatment of carcinoma of the cervix. In discussing vaginal carcinomas he considered five subgroups depending upon the degree of involvement, and in certain cancers in this group offered a possibility of permanent cure. He quoted statistics showing 15 per cent. of apparent cures in cases that would formerly have been considered incurable, and concluded that radium was a most welcome addition to the methods of treating cancer; a combination of radium and the *x*-ray was better than radium alone; a combination of radium and early operation gave better results than radium alone or operation alone. Radium could lead to painful and even fatal results if improperly used; therefore surgeons should learn how to employ this treatment safely. Would it not be possible for the College of Surgeons to take up the standardization of cancer reports?

Plastic Operations for Facial Burns.—Major GILLIES of Sidcup, England, gave this presentation, which consisted in a lantern-slide demonstration of his methods and results in the treatment of severe facial burns by various plastic operations. In some instances the Wolf graft was used and in some the Thiersch graft. The method of employing the tube-pedicle was demonstrated and its advantages in plastic surgery described. By means of a tube-pedicle it would be possible to reconstruct an esophagus. Procedures by which cartilage was employed in rhinoplasty were described and a slide shown of an upper abdomen and chest in which pieces of cartilage were imbedded awaiting use—a cartilage larder.

Convocation.—Dr. FRANKLIN H. MARTIN presented 400 candidates for fellowship in the American College of Surgeons, fifty of whom were from the Army and fifty from the Navy. Dr. William J. Mayo received the applicants into Fellowship. Honorary Fellowship in the American College of Surgeons was conferred upon Sir Anthony Bowlby, Sir Robert Jones, Major General Tuffier of Paris, and Dr. Irving H. Cameron of Toronto. Surgeon General Ireland awarded the Distinguished Service Medal to Sir Anthony Bowlby and Sir Robert Jones in recognition of the assistance given America in the treatment of her wounded soldiers.

Presidential Address.—Dr. WILLIAM J. MAYO delivered this address, in which he said that the American College of Surgeons was beginning its seventh year under inspiring circumstances. In spite of the war it had made progress in all lines. The Clinical College of Surgeons had been taken over by the American College of Surgeons. Only members would be welcome to its clinical meetings. The organization was open to all men of sterling ability within the limits of North America. Unless a sufficient number of men of high ideals and adequate professional attainments were affiliated with it, it would fail of its purpose. There should be one surgeon to 1,000 persons. This was about the proportion they had in the Royal College of Surgeons of England. The next generation would not be so much troubled about educational standards as this one had been. He believed for the present that a man who brought a high order of skill in surgery should not be refused because of a lack of fundamental training. He thought, however, that their educational standards should be raised from time to time. Their educational requirements now included graduation from college, and from medical college and then special training in the branch of surgery the surgeon expected to practise. Three years at least would be required for such special training. Under the present system, if three years were added it brought the man to the age of thirty-one years before he was prepared to practise surgery, and the question was whether the man would not reach his life work too late. Another question that arose was whether the cost of this education would not make of surgery an aristocracy, a profession open only to the sons of

rich men. One investigation carried out among college graduates showed that those men who had been graduated before the age of twenty-five years were a greater asset to their community than those who had been graduated at a later age. All were agreed that the time devoted to medical education should not be shortened. It was also agreed that much time was lost during the period of preliminary education. Dr. Mayo proposed a plan which, he stated, was in successful operation in a Minnesota town whereby the primary and grammar grades could be completed in six years. He insisted that the instruction should be given in the English language. It should be a common education given along common sense lines and might be made a requisite for suffrage. Languages should be optional, though he believed Latin would be necessary for a professional man. There was an idea prevalent among cloistered scholastics that an education along practical lines with a commercial object in view could not be cultural. This idea was outworn. The great problem was to get money enough to equip the universities so that they could accommodate all those who desired an education. To meet this problem standards should be raised until the number of those who could take a university education was reduced. It should be the duty of the American College of Surgeons to see that certain faults in preliminary education were remedied so that they could graduate medical students at an earlier age. Many South American universities were preeminent as educational institutions. If it wished to be truly American the American College of Surgeons should affiliate with these South American universities. He felt sure that a way would be found to this end.

Fellowship Address.—Sir Anthony Bowlby delivered this address, in which he said that the late war that shook the world had passed, the Ship of State had weathered the storm and lay in harbor, and the time had arrived to see what they had learned by the experience. Millions had died in battle and tens of thousands had been wounded. He would consider the lessons that had been learned in the treatment of these wounded men, confining his remarks to France and Belgium. The world had a right to expect that it would profit by their war experience. Far more had been learned than any one would have dared prophesy before the war. The system of caring for the wounded from the front lines to the base hospital had been organized with a perfection that would never have been thought possible before 1914. Before that time it was thought impossible to treat the wounds of war as the wounds of peace were treated. It was not realized that that was just what they should have expected to do; that was now their ideal. It paid a country to treat the wounds of its fighting men as well as possible, since it helped the army to return the men to the front sooner and in greater numbers, and it was a great saving in pensions. In principle the same thing applied to the wounds of industry. The fact that the wounded soldier frequently suffered from lack of food and exposure in addition to his wounds often caused shock out of all proportion to the extent of his wounds. Often, with complete rest, hot drinks, and plenty of water, the soldier would recover from shock. Much wound shock could be obviated by a supply of well warmed and well equipped ambulances. He had just equipped 500 motor ambulances, with well trained drivers and orderlies, for the transportation of persons injured in industry, and he suggested the same plan to his hearers. One could train these men to apply first aid dressings as well or better than professional surgeons had been accustomed to apply them before the war.

Loss of blood volume and fall of blood pressure were treated by rest. As all the soldiers had limited supplies of water they required water as soon as they arrived at the first aid station or ambulance. Rectal injections were useful if the patient had lost much blood. The blood pressure and blood volume were improved more by rectal than by intravenous injections. Physiological saline solution was practically useless. It was the opinion of Bayliss and of most observers that 6 per cent, gum arabic in saline solution was of benefit in maintaining the blood pressure. Transfusion of blood had been of benefit where there had been an excessive loss of blood. Properly tested and citrated blood was sent up to the front and could be used from twelve to eighteen hours after it had been citrated. He had suggested that a sterilized gum solution be kept ready for use. Where limbs were hopelessly shattered or the abdomen perforated, the patients had to be operated on as soon as possible, even at the risk of additional shock. Most of the men had excessive bronchial exudates, as they were wet almost all the time, and in order to make the administration of the anesthetic safer the ether vapor was warmed. Later they decided that ether was not a safe anesthetic, not only because of the possible danger at the time of administration, but because of the sickness after the operation, which often took away the patient's last chance for life. They then employed nitrous oxide and oxygen. With this anesthesia even extensive operations could be performed, and they believed this had been the means of saving many lives. In abdominal operations the best results followed with the use of nitrous oxide and oxygen anesthesia with infiltration anesthesia of the abdominal walls. It was by the use of this combination that they were successful in saving 74 patients out of 104 with abdominal wounds.

In the treatment of fractured arms use was made of suspension and extension, and there were no longer contractions caused by bandages. Legs were no longer encased in wooden boxes or in plaster of Paris, and in consequence wasting muscles and defects in the joints had been greatly diminished in all the hospitals. The setting of a fractured limb, as taught in the medical schools, was only the beginning and not the end of surgical treatment. As long as the principles were kept in view the details must be left to the individual surgeon. A too early standardization of the operative methods employed in the war would spell stagnation. The principles would remain while the methods would change. Looking back to the beginning of the war they had much to unlearn before they could learn, and many were unduly influenced by their previous experience.

Their experience had taught them the necessity of excising all devitalized tissue and the uselessness of attempting to sterilize wounds by the use of powerful chemicals. Lister himself had long ago said that if an infected scalpel conveyed pus to a wound it was not likely that it could be sterilized by any antiseptic we now had or were likely to have. The next question was how to treat wounds after they had been properly cleansed mechanically. The answer was by early primary or late primary closure. Wounds healed well and permanently even if there were some organisms present, so long as they did not contain the virulent streptococcus. The results obtained might be summed up by saying that not only were many lives saved by these methods of wound closure but a further lesson from the army point of view was that fewer beds were occupied and nursing service was spared. Furthermore, many soldiers were returned to the front within a few weeks instead of suffering for months. He wondered if in the future they would close knee wounds and delay primary suture in extensive wounds in civil life?

With reference to suppurative wounds they had learned two things. The first was that it was more often possible to close them by suture than they had thought in advance. He had seen successful primary closure of compound fractures. Second, that the Carrel treatment supplied a thoroughly scientific and carefully thought-out method of great use if applied at the right time. They had learned much that would be useful in the treatment of suppurating wounds in civil surgery, and much that might be made use of in the prevention of suppuration. He believed in the future the surgeon would work more with the bacteriologist. While many advances had been made, there was still much to be learned. The safe attitude was that, however good a method might be, it was always possible to evolve another that might be better still. The surgeon of the immediate future might expect that there would be improvement in the transportation of the wounded and that shock would be better treated. If he were to enter into the surgery of the head, chest, abdomen, and the different regions, Sir Anthony said, he could cite many instances showing notable advances in surgery, but he had only attempted to mention the general principles.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO BOARD OF MEDICAL EXAMINERS.

Denver, October 7, 1919.

(*Concluded from page 382.*)

OBSTETRICS.

1. (*a*) What do you understand by accidental hemorrhage and its causes in obstetrical practice? (*b*) Give briefly symptoms of the following varieties of accidental hemorrhage: (1) slight cases, (2) fulminant cases, (3) recurrent cases.

2. (*a*) Give definitions for cephalic, bipolar cephalic, and podalic versions. (*b*) Name five important indications for podalic version.

3. (*a*) Under what conditions would you hasten delivery in the interest of the child? (*b*) Why best to place your patient in Walcher's position if you are to apply forceps at brim of a contracted pelvis?

4. Give briefly your technique in a podalic version.

5. Name the four types of vertex presentation and how you would diagnose a R. O. P. position.

6. What are your instructions to the nurse after normal delivery as to the care of mother and child for the period of three days?

7. What do you understand by a subinvolution of the uterus and what means would you use to deliver it?

8. Name a few causes of sore nipples in a nursing mother. Do or would you recommend any special preventive steps before the birth of the child?

9. What indications during the second stage of labor might appear to justify you in the use of a high forceps delivery.

10. Describe the symptoms of a ruptured uterus during labor.

SURGERY.

1. What is gangrene? Its causes and varieties.

2. Give differential diagnosis in gastric crises, acute appendicitis, acute cholecystitis. What chest conditions may give symptoms simulating any of the foregoing?

3. What symptoms accompany pathological conditions of the pituitary body?

4. Give differential diagnosis in tuberculosis and syphilis of the larynx.

5. Give causes of varicose veins.

6. Name the varieties of talipes and give causes of each variety.

7. With what conditions may brain abscess be confused? Give differential diagnosis.

8. Define the terms thrombus, phlebitis, and varix with causes of each.

9. Give the symptoms and differential diagnosis of septic surgical fever.

10. Discuss prolapse of the rectum in children, giving causes and indication for surgical interference.

ANSWERS.

OBSTETRICS.

1. *Concealed hemorrhage* is a bleeding resulting from the partial or complete separation of a normally seated placenta, occurring in the later months of pregnancy or at the beginning of labor. *Causes:* Loose attachment of the placenta, violent muscular effort, violent uterine contractions, short cord, excessive distention of uterus, external violence as blows and falls, diseases of decidua or placenta, nephritis, toxemia, and acute infectious diseases.

Apparent variety.—"Accidental hemorrhage usually occurs before labor begins or in the first stage. It is necessary to distinguish it from rupture of the uterus and from placenta prævia. The former occurs later in labor and is attended with recession of the presenting part, with diminution of the uterine tumor, and the development of a new abdominal tumor. The latter is readily recognized or excluded by a physical examination. Bleeding from low implantation of the placenta may easily be mistaken for accidental hemorrhage."

Concealed Variety.—"The principal signs are: Extreme pallor; shock of some degree; persistent tension of the uterus, while the rhythmic contractions become weak; a node or boss forms on the uterine surface at the site of the retroplacental blood collection, or the uterus becomes atonic and is distended by the accumulation of blood. The uterine tumor may be boggy, or tense, especially in the upper segment; the fetal parts are obscured in palpation; there may be continuous pain and tenderness in certain cases from distention of the perimetrium; *bloody liquor amnii may be detected by pushing up the presenting part and allowing a portion of the liquor amnii to escape;* the fetal heart-tones are feeble and irregular, or absent.

"Together with these signs are the signs of internal hemorrhage, viz., collapse; pallor; surface, especially of extremities, cold and clammy; excessive perspiration; respiration irregular; sighing; sobbing; yawning; pulse rapid, thready, and compressible; thirst; jactitation; tinnitus aurium; dyspnea; nausea; dimness of vision syncope.

"It should be remembered that a concealed hemorrhage may coexist with an insignificant apparent hemorrhage."—(Polak's *Manual of Obstetrics.*)—

2. *Cephalic version* is the operation of version, in which the head of the child is brought down.

Bipolar cephalic version is the name given to cephalic version when the operator manipulates with one hand on the anterior abdominal wall of the patient, and the other hand in her vagina; two or three of his fingers are passed into the uterus.

Podalic version is version in which the feet of the child are brought down.

Five indications for podalic version: (1) in placenta prævia; (2) in malpresentations of the head; (3) in simple flattened pelvis, and in minor degrees of pelvic contraction; (4) in prolapsed funis; (5) in any case where speedy delivery is imperative.

3. *Delivery should be hastened, in the interest of the child,* in: Placenta prævia; moderately contracted pelvis; toxemia of pregnancy; when the mother is suffering from severe cardiac respiratory or renal disease. Also when the fetal pulse is very rapid, and the heart sounds are weak.

4. *Braxton Hicks' method of bipolar (podalic) version:* "The patient should be placed in the lithotomy position and be deeply anesthetized, to relax the parts and allow the whole hand to be pushed into the vagina. The external hand is placed over the breech, so as to depress it; while the presenting part is tilted away from the brim by the fingers inserted through the os. The fingers press against the front of the child and flexion is lessened. When the head is out of the brim the external hand can be used to elevate it towards the fundus. As soon as a knee or foot comes within reach of the internal fingers, it should be caught and brought into the brim, the membrane being ruptured at the same time. If the os is fully dilated, delivery may be finished at once, as in an ordinary breech case; but if the os is only partially dilated, it must be left to nature, to allow of dilatation."—(Jardine's *Delayed and Complicated Labor.*)

5. *The four types of vertex presentation,* are: (1) Left occipito-anterior; (2) Right occipito-posterior; (3) Right occipito-anterior; (4) Left occipito-posterior.

To diagnose a R. O. P. position: Abdominal examination shows the fetal back on the right side and posteriorly, with the extremities above and to the left anteriorly. The fetal heart sounds are best heard in the right flank below the umbilicus. Vaginal examination shows the dome of the vertex presenting, with the smaller fontanelle posterior and pointing to the right sacro-iliac synchondrosis; the sagittal suture is in the right oblique diameter, and the anterior fontanelle is high up anteriorly near the left acetabulum.

6. DIRECTIONS FOR THE NURSE.—The following are given by Hirst (*Text-book of Obstetrics*):

No vaginal injection to be given unless ordered. Take the temperature three times a day—morning, noon, and evening. Place pad of nursery cloth *under* patient; change it when soiled. Occlusive bandage to be made up of salicylated cotton and carbolized gauze, with sterile hands, and to be changed, for the first five days, every four hours. The external genitals to be washed off four or five times a day with warm corrosive sublimate solution, 1:4000, made up with boiled water. Use absorbent cotton for this purpose. If, at the end of twelve hours, the bladder cannot be emptied naturally, use a catheter Afterward, if necessary, catheterize

patient three times a day. The patient is to lie on her back; she may be moved from one side of the bed to the other several times a day; her limbs may be rubbed with alcohol and water or bathing-whisky once a day.

The nurse's hands must be protected by sterile rubber gloves before catheterizing the patient, cleansing the genitals or breasts.

Diet.—First 48 hours.—Milk (1½ to 2 pints a day), gruel, soup, one cup of tea a day, toast and butter. *Second 48 hours.*—Milk tost, poached eggs, porridge, soup, cornstarch, tapioca, wine-jelly, small raw or stewed oysters, one cup of coffee or tea a day. *Third 48 hours.*—Soup, white meat of fowl, mashed potatoes, beets, in addition to above.

Child.—After being well rubbed with sweet-oil, the child is to be washed on the nurse's lap. The bath-tub may be used by the end of the first week. Water not over 100° F. The cord is to be dressed with salicylated cotton. Observe carefully for bleeding. A good dusting-powder for the navel is salicylic acid 1 part, starch 5 parts. The child should be bathed daily, about midday, in the warmest part of the room. Use castile soap and a soft sponge; avoid the eyes. Diapers changed often enough. For chafe, use cold cream and talcum powder.

Nursing.—The child is to be put to the breast every four hours for the first two days. *No other food is to be given it.* After the second day it should be nursed every two hours, from 7 A. M. to 9 P. M., and twice during the night (1 A. M and 5 A. M.). After every nursing the nipples are to be carefully dried and then smeared with a little sweet-oil for the first week or two, applied with fresh pledgets of absorbent cotton.

7. When the uterus does not return to (approximately) its normal size and condition within about six weeks after labor, the condition is called *subinvolution. Subinvolution* is caused by fibroid tumors, pelvic inflammatory conditions, early resumption of sexual intercourse, premature rising from bed, retained secundines, uterine displacements and adhesions, etc. It is characterized by enlarged uterus and irregular bleeding. In all cases rest in bed, copious hot vaginal douches, abstinence from sexual intercourse, correction of constipation, and the administration of tonics are beneficial. Any treatment should be preceded by thorough curettage. Displacements should be corrected.

8. *Causes of sore nipples:* Cracks, fissures, erosions, and chafing, are often due to poor development of the nipples, and to maceration and lack of cleanliness. During the latter part of pregnancy the nipples should be bathed constantly with soap and water, gently massaged with oil, or rubbed with alcohol; boric acid, glycerin and tannin or some other hardening or disinfectant agent may be used. The nipple must be kept clean and dry.

9. *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A.—Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B.—Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."

10. *Ruptured uterus* is announced by a sudden, acute, and persistent pain. Sometimes the sound of the rupture is heard by the patient; the symptoms of internal hemorrhage and shock are present—collapse, air-hunger, cyanosis, rapid, feeble pulse; the uterine contractions cease. Vaginal examination shows that the presenting part of the child has receded from its former situation owing to escape of the fetus (partially or completely) through the rent into the abdominal cavity, where it may be felt by abdominal palpation.

SURGERY.

1. *Gangrene* means death of macroscopic portions of tissue.

The varieties are: Moist and dry (clinically); and direct, indirect, and specific (etiologically).

Dry gangrene occurs when death happens in a part which has been previously drained of its fluids. The usual cause is arterial thrombosis supervening on atheroma or calcification of vessels.

Moist gangrene occurs when the dead part is full of fluid, and may be aseptic or septic, generally the latter.

Direct gangrene may be due to: Crushing of the part; pressure; acute inflammation; the action of heat or cold.

Indirect gangrene is death of a part due to a cause acting at some distance—*e. g.*, gradual diminution in the caliber of the blood vessels; sudden obstruction in the blood vessels; imperfect innervation; general causes such as diabetes, acute fevers and the use of ergot.

Infective gangrene is due to specific infective organisms: Acute traumatic gangrene due to the bacillus of malignant edema; phagedena; cancrum oris or noma.—(From *Aids to Surgery.*)

2. *Gastric crises.*—Lightning-like attacks of agonizing, cramping, epigastric pain, associated with nausea or violent vomiting, at first of but a few minutes' duration, later persisting for hours or days, separated at first by long intervals, but progressively increasing until for a period of weeks they may occur daily.—(Greene's *Medical Diagnosis.*)

In *appendicitis:* The pain is at first diffuse, but later becomes localized over the appendix in the right iliac fossa; nausea, vomiting, and constipation may be present; tenderness over the appendix and rigidity of the right rectus abdominis muscle are present; there is generally moderate fever.

In *cholecystitis*, the pain is in the right hypochondriac or epigastric region, and occurs in paroxysms and without reference to time of eating; nausea, vomiting and jaundice may be present; constipation is common; and there is generally severe prostration.

"When the three cardiac symptoms of the disease are present—that is, sudden onset of acute abdominal pain, followed by vomiting, occurring in one previously well; unilateral rigidity of the right lower abdominal wall; tenderness over the site of the appendix—the diagnosis of *acute appendicitis* is warranted in nearly every case."—(Deaver's *Appendicitis.*)

Thoracic Conditions.—"Cases of both pneumonia and pleurisy occur, in which there is complaint of severe pain in the abdomen at the onset of the disease. This is especially true in children. There may be rigidity of the abdominal muscles on the side affected. In pneumonia there is a history of a chill. The acute onset is followed by dyspnea, and marked increase in respirations and pulse-rate. The pain is seldom as well localized as in the acute abdominal conditions, nor is the muscular rigidity as circumscribed and constant.

There is one form of pleurisy (diaphragmatic) which simulates acute abdominal affections very closely. The breathing is shallow and costal, the pain is severe and referred to the upper abdominal region."—Eisendrath's *Surgical Diagnosis.*)

3. In *hyperpituitrism*, or excessive secretion of the pituitary gland, there may be a narrowing of the field of vision, followed by acromegaly; this latter consists of a marked overgrowth of the head and extremities, the face becomes larger and coarser, the skeleton increases in size, the patient becomes like a giant, the terminal phalanges of the fingers become "mushroomed," the skin becomes thickened, there is an increase of hair on the body, and sexual activity is diminished. In *hypopituitrism*, or diminished secretion of the pituitary gland, the patient shows small stature, development of fat, lack of hair, delayed or deficient sexual development, the temperature is subnormal, blood pressure is low, the mental attitude is sluggish and there is a tendency to drowsiness.

4. TUBERCULOSIS OF LARYNX.	SYPHILIS OF LARYNX.
Pain severe on deglutition.	Pain usually slight.
Favorite site in the interarytenoid space, and base of arytenoid cartilages.	Attacks any portion of the larynx.
Ulcerates slowly.	Ulcerates rapidly.

TUBERCULOSIS OF LARYNX.	SYPHILIS OF LARYNX.
Usually first appears as small spots or nodules which are rapidly followed by great edema.	Is rarely seen in stage of induration, the first evidence being a clear-cut, deep ulcer.
Great edema of arytenoids.	Some induration around ulcer, but usually very little edema.
Ulcers extend laterally but not deeply.	Ulcers extend deeply, often involving cartilage.
Surface of ulcer covered with thick mucopurulent secretion and agglutinated mucus.	Surface of ulcer covered with mucopurulent secretion and necrosed tissue.
Mucous membrane usually pale.	Mucous membrane hyperemic, injected.
Laryngeal stenosis rarely occurs.	Laryngeal stenosis uncommon until cicatrization occurs.
Health impaired previous to laryngeal involvement.	General health unimpaired.
Previous or coincident pulmonary trouble common.	Frequently evidence of syphilitic disease in other tissues.
Iodides have no influence.	Readily improves under iodides.

—(From *Reference Handbook of Medical Sciences.*)

5. *Causes of varicose veins*—Overdistention, caused by long standing; increased abdominal pressure from tumors or pregnancy; congenital overdevelopment of the veins; failure of the valves in the veins; blocking of deep veins by a thrombus.

6. VARIETIES OF TALIPES, WITH CAUSES.—(1) *Talipes Equinus*, generally acquired, rarely congenital; infantile paralysis of extensor muscles of foot; partial paralysis of leg muscles, the calf muscles overcoming those on the anterior surface; spastic contraction of the calf muscles; compensatory to shortening of the leg, as in hip disease; from pressure of the bedclothes, as in talipes decubitus. (2) *Talipes equinovarus*, may be congenital or acquired; paralysis of extensor and peroneal muscles; injury to external popliteal nerve; overaction of calf muscles; (3) *Talipes calcaneus*, rarely congenital, usually the result of infantile paralysis of the calf muscles. (4) *Talipes valgus*, rarely congenital, results from paralysis of the tibialis posticus and the flexors, with secondary contraction of the peronei.

7. BRAIN ABSCESS.—"The *symptoms* in traumatic cases are acute and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The *headache* and tenderness are severe and localized to the site of the abscess. 2. The *temperature* is subnormal, unless there is associated meningitis. 3. The *pulse* is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but *cerebration* is very slow; vomiting and optic neuritis are usually present. 5. *Motor symptoms* may occur if the abscess is in the anterior part of the temporosphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand grip and increase in the knee jerk on the side affected. Lateral nystagmus often occurs."

It is to be diagnosed from meningitis, extradural abscess, and lateral sinus thrombosis:—From *meningitis*, by the fact that in meningitis there is fever, great restlessness, delirium, photophobia, pain and spasm in the muscles, especially at the back of the neck. An *extradural abscess* is always accompanied by fever. In *lateral sinus thrombosis* there are rigors and profuse sweats, and there may be a hard tender cord in the situation of the internal jugular vein. Chronic abscess and tumor are often indistinguishable in their symptoms, but the presence of chronic otitis media suggests abscess.

8. A *thrombus* is a clot formed within the lumen of a blood vessel during life.

Causes of thrombosis: (1) changes in the walls of the blood vessels, due to the presence of infection or foreign bodies; (2) changes in the blood, whereby its tendency to coagulate is increased; (3) diminished rate of the blood flow, due to weak heart action or obstruction.

Phlebitis is inflammation of the wall of a vein. It may be *caused* by injury, pressure, thrombosis, gout, septic wounds, inflammatory lesions outside the vein. It often accompanies varicose veins.

Varix or *varicose vein* is a dilated or tortuous or elongated vein. For *causes*, see Question 5.

9. *Septic traumatic fever* is the fever which accompanies an ordinary septic wound. It is most marked when the wound is closed. The temperature rises to 101° to 103° F., often with a rigor. It falls rapidly when the wound is opened, and is at an end when the layer of granulations prevents further absorption. *Sapremia* is caused by the absorption of a large dose of toxin. A large or virulent infective focus exists (*e. g.*, a septic placental remnant in utero, or a localized appendicitis), and from this toxins (but not bacteria) enter the circulation. A rigor with rapid rise of temperature to about 104° F. is the first symptom. In the worst cases the temperature remains subnormal. Vomiting and diarrhea, delirium or coma, dyspnea, or albuminuria may occur, according to the organs which react most to the toxins. Dry tongue, quick pulse, scanty urine, and headache are the rule. All the symptoms subside rapidly when the infective focus is freely opened and cleared out. *Septicemia* is caused by the absorption and development of bacteria in the blood of the patient. Local inflammatory signs may be of any degree. Temperature rises to 104° to 105° F. with a rigor, and remains fairly high without marked intermissions. The temperature becomes subnormal, while the pulse rises, in fatal cases. The symptoms are the same as those of sapremia, but of a further intensity. In sapremia and septic traumatic fever there are three points to help in the distinction: (1) The presence of an inflamed wound or local infective focus in which the local signs are in proportion to the constitutional; (2) the rapid amelioration of the symptoms on freely opening the infective focus; (3) the fact that repeated blood examinations give a negative bacterial result. *Pyemia* is distinguished by the repeated rigors, the intermittent temperature, and the local abscesses.—(From Grove's *Synopsis of Surgery.*)

10. *Prolapse of rectum in children.—Causes:* In most cases several factors contribute to the production of the prolapse, the most important and constant of which are undue laxity of the perineal and rectal tissues, including the sphincters and levator ani muscles, and some cause of repeated and excessive straining. In young children, for example, after any exhausting illness the perineal muscles become weakened and relaxed, and the pads of fat that surround the rectum disappear, and the bowel is thus deprived of its natural support. If, under these conditions, the patient suffers from constipation, diarrhea, rectal polypus, worms, phimosis, stone in the bladder, or any other condition that induces severe straining, prolapse of the bowel is very liable to develop. The violent muscular efforts caused by whooping-cough or bronchitis may also determine prolapse in a weakly child. The condition has also been attributed to the pernicious habit of allowing the child to sit at stool after the bowel has been emptied.

Treatment—The *reduction* of a prolapse is best effected by raising the pelvis—a child may be held up by the heels—smearing the protrusion with vaseline, and applying gentle pressure over the apex of the cone. After the mass has slipped through the anus, a soft pad is placed between the nates and fixed securely in position by a T-shaped bandage, or the buttocks may be pressed together and held in this position by a strip of adhesive plaster passed from one trochanter to the other. The patient should remain recumbent for an hour or two after reduction. Constipation or any other existing cause of straining must be corrected, and means taken to ensure easy and regular movement of the bowels. The child should be made to defecate while lying on the back or on the side. Injections of ice-cold water, or of solutions of alum or sulphate of iron, are sometimes useful. In children it is seldom necessary to operate.—(Thomson and Miles' *Surgery.*)

INFLUENCE OF THE MALE ON THE PRODUCTION OF TWINS.*

BY CHARLES B. DAVENPORT,

COLD SPRING HARBOR N. Y.

ABOUT 1 per cent. of all human births are plural births. As is well known, twins are of two types: namely, those which are derived from two eggs ovulated simultaneously or nearly so, and those derived from a single egg which has formed two embryos. In the former case, each embryo is enveloped in its own chorion; in the latter, both embryos are enveloped in one and the same chorion. Frequently a mother will have more than one pair of twins. This condition may be called repeating. The statistics given in this paper are largely derived from families of repeaters. The existence of repeaters indicates that the production of twins is determined in part at least by the constitution of the mother, since she must have an ovarial structure that readily permits double ovulation. It is easy to understand how such a structural idiosyncrasy of the mother might reappear in her own daughters and thus that the tendency to twinning should show itself as an hereditary trait.

If now the close relatives of repeating mothers be taken as a population for study, it is found that in them the ratio of twin production rises to 4.5 per cent., which indicates that such mothers belong to strains in which the factors that make for twinning are four times as effective as in the population at large. If, on the other hand, one considers as a population the close relatives of fathers of twins, then one still finds that the incidence of twins in this selected population is much above that in the population at large, namely 4.2 per cent.—a ratio nearly as high as that found for the relatives of the mothers. It appears then that, in twin production, the paternal inheritance is real and nearly as potent as the maternal. The question at once arises—how can this be? We can understand inheritance of a tendency to double ovulation, but why do the fathers also of twins so generally belong to twin-producing stocks? It may be added that this phenomenon seems to occur both in the case of binovular and uniovular twins. It has been alleged by some that there is no inheritance in the production of uniovular twins, but our family statistics give the rate of twin production in the families of either father or mother of identical twins at not far from 13 per cent. Though the rate is based on only 30 families, yet it indicates that inheritance is even more marked in uniovular than in binovular twins.

But to return to our problem of the possible rôle of the male in twin production. The frequently denied possibility of such influence depends on a tacit assumption which seems never to have been challenged by students of twin inheritance. This assumption is that the determining differential fact in twin production as contrasted with single birth production is the constant double ovulation in the first case and the constant single ovulation in the second. Whenever two eggs are simultaneously ovulated at a period when fertilization occurs, there will be twins. Under such an hypothesis, it will be difficult to understand how the results are influenced by any tendency toward twin production from the father's side of the house.

If, on the contrary, the hypothesis were formulated (false as it would be) that in women two eggs are always simultaneously ovulated, then the frequency of occurrence of single births would be accounted for on the ground of some peculiarity in the male, and it would be recognized that the mother had little or nothing to do with determining the deviation from two in the observed number of young at a birth. Now, the hypothesis just proposed is, as stated, false and the facts which I shall offer in the present paper demonstrate that the first hypothesis (that the number of eggs ovulated by the female determines the number of births) is no less false. The facts lie between the two hypotheses. Double ovulation is far commoner, proportionately, than twin births, and here we see the opportunity for the influence of the male.

We have all too inadequate statistical data concerning the frequency of double ovulation. The most extensive series of statistics is that obtained by Leopold and his pupils. To this collection additions have been made from the more scattered observations of others. Taken altogether, it appears that probably between 5 and 10 per cent. of ovulations are double, as proven by the fact that, in ovaries of women of child-bearing age which have been carefully examined, relatively recent corpora lutea of the same age have been found in between 5 and 10 per cent. It appears that the proportion of twins actually born is less than one-fifth as great as the proportion of double ovulations.

The question now arises—what has happened in the 80 per cent. or more of the cases in which potential twin production has not been realized? The answer to this question is to be secured by comparative statistics on the number of corpora lutea

*Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, February 24, 1920.

in relation to the number of embryos in mammals which regularly produce many young at a birth. Accordingly a study has been made of the pregnant uteri of swine and a comparison made between the number of embryos in the course of development and the number of recent corpora lutea. The result of a number of observations is given in the following table:

Observation number	Number of recent corpora lutea	Number of embryos found	Average length of embryos
1	3	3	15.0 cm.
2	6	3	10.0 cm.
7	8	7	6.5 cm.
12	9	2	2.5 cm.
13	8	7	2.0 cm.
	34	22	

From this statement it appears that there is a regular deficiency of from 1 to 7 embryos as compared with the number of corpora lutea. The reason for the deficiency in the number of embryos is no doubt complex. One element becomes very clear when an examination of uteri reveals some embryos that are 20-30 mm. long and, in the same uterus, those which lag far behind their fellows and may be only 5 mm. long, have stopped developing, and may even be undergoing a secondary degeneration. This is a fairly common phenomenon in the series of embryos to be found in the horns of the uteri of swine and other multiparous animals. Similar blighted fetuses have doubtless been found by every obstetrician of experience. Scores of cases of blighted twin fetuses are recorded in the literature, and if only the placentæ and envelopes of supposed single births were systematically scrutinized, it is certain that such blighted fetuses would be much more commonly observed than at present. Also among humans we have the phenomenon of miscarriages. These occur in all embryonic stages, from one in which they are recognized only as a disturbance that is followed by the resumption of the interrupted menstrual series to the stage of premature still birth. Such miscarriages are due to a large number of causes, but doubtless one cause is that of sheer inability to continue development because of internal weakness of the embryo. The causes of still births are numerous, and there has long been recognized a category of still births for which there is no sufficient external cause of the nature of infection, traumatism, or constitutional disease of the mother. The fetus simply dies through a lack of sufficient developmental impulse, very much as a marasmic baby dies after birth, despite the best of care. We must recognize as a regular phenomenon the incapacity for development on the part of certain zygotes which have been implanted in an apparently healthy environment.

Such incapacity for development has been observed by geneticists in a large number of cases and they recognize the category of lethal factors which, brought in by one or both parental germ cells, inevitably prevent full development. Such lethal factors correspond to gross variations in essential visceral organs and run parallel to such gross variations of external organs as cleft palate, microphthalmia and absence of appendages. One of the earliest described cases of lethal factors was that which prevents the development of yellow-haired mice which get the yellow factor from both parents. Earless sheep (apparently) and numerous cases in the fruit fly, *Drosophila*, are other examples of bearers of lethal factors. Lethal factors may kill at any age—at the second, fourth, or sixth month, at the time of birth, or in the first month or two after birth. It is time that gynecologists and obstetricians recognized the great importance of lethal factors in human development. These factors help to explain many cases of physiological sterility and repeated tendency to miscarriage, still birth, and marasmus.

Now lethal factors may be brought into the zygote by the egg alone, by the sperm alone, or by both. They are not found in all the germ cells; it may be, in only a small proportion of them. When they occur in the gametes of both consorts, small families with some feeble children may be expected. But when they are absent in the germ cells of both parents, then, in a good environment, the fertilized egg will develop vigorously with good prospects of reaching maturity. Now it is in such families that any tendency toward double ovulation will be expressed in the production of healthy twins. It may be noted in passing that statisticians have long recognized that the proportion of twins is larger in highly fecund families than in those that produce few offspring, and this is now seen to be because in such highly fecund families the germ cells contain few lethal factors and there is a larger chance that double ovulation will result in twins.

In addition to lethal factors one must recognize that there is probably a frequent failure of fertilization of the egg, even when conditions would seem to be propitious. This is indicated by the fact that in swine one practically always finds more recent corpora lutea than embryos in any state of development. One or more of the eggs have probably not been penetrated by active spermatozoa. We must conclude, therefore, that in a certain proportion of double ovulations one of the two eggs may fail of fertilization, while the other goes on to development.

The preceding considerations make it clear where the male factor comes in in twin production, for the father can, as much as the mother, determine whether both of a pair of simultaneously ovulated eggs shall be fertilized, and whether or not they shall receive lethal factors.

A word may be added concerning one-egg twins, which are always of the same sex and are sometimes called identical twins. The theory of identical twins has varied from time to time. Some years ago it was shown experimentally that the two first cleavage spheres of sea urchin eggs might be more or less completely shaken apart and each sphere develop into a complete individual. This result was applied to man as an explanation of identical twins and double monsters. Within the last ten years, however, through the observations of Newman and Patterson on the armadillo, an animal which regularly produces four embryos from one egg by a process of budding, the theory of budding has been applied to the explanation of identical twins in man; and some fragmentary observations of very early human embryos support the view. Meanwhile attention is called to the fact that it has been several times observed in

human quadruplets that three fetuses are enveloped in a common chorion. It is difficult to explain this result on the hypothesis of mechanical pressure on the developing egg, since this would separate three cleavage spheres from the group of four or eight. It is known from the work on armadillos that the number of buds, though usually four, is not absolutely fixed, but there are sometimes three and sometimes five. Apparently in man the typical number of buds is two, but there may occasionally be three.

Attention is called in passing to the exceptional interest which attaches to multiple births in man. Twins occur in other ordinarily uniparous animals, such as sheep, cows, and horses. The examination of a large amount of statistical data shows that in these animals twins of similar and dissimilar sex are equally numerous, so that one concludes that all these twins are derived from two eggs and that uniovular twins rarely occur. In the armadillo, on the other hand, we have a species in which binovular twins are unknown and uniovular plural births are the universal type. Each fertilized egg ordinarily produces quadruplets.

In humans both types of plural pregnancy occur, the method of twin reproduction found in the armadillo, and the method found in the sheep, carnivora, herbivora, and rodentia in general. Moreover, these two types are both fairly common, since out of every four pair of twins three are of the binovular and one of the uniovular type. Thus, man seems to have a double heritage and through him runs a double strain of twin production. It would be interesting to learn whether in all races of mankind the relative frequency of the two types is the same as it is in Europeans.

Finally, I would like to make a plea for more careful observations of afterbirths by obstetricians. Too often the afterbirth is thrown away without inspection. When possible, it should be rinsed in water and then placed in a basin of clear water and the fetal aspect of the placenta examined for a possible blighted fetus. If found, its presence should be recorded, and when possible, it should be carefully measured. Also a plea is made for more exact observation of the afterbirth in the case of twins. I find that, admirable as are the records of lying-in hospitals in this city, they are frequently unreliable in their statement as to the number of chorions. Thus, not infrequently twins of different sex are said to have one chorion. The criterion of double chorions is, of course, the presence of four membranes (though they may be extremely thin and stuck together) separating the two amniotic cavities. On the other hand, when a chorion is single, the partition contains only two layers. Also, in this case, a triangle may be made out at the point where the two amnions leave contact with the common chorion to come together to form a common partition.

The importance of an accurate statement on record as to whether the twins were binovular or uniovular is two-fold. First, it will, in common with the racial data, tell us whether the two types are equally common in different countries. In the second place, adult twins may want to know, and have the right to know, whether they are identical twins or not. Repeatedly I have been asked by intelligent twins if there were not a test that could be applied that would enable them to decide to which category they belong. There are occasions when such knowledge might be of more than social, indeed of important medical, interest. Obstetricians owe that much to the twins which they help bring into the world to leave an accurate record of their findings as to the true nature of the twins. Finally may be urged the real need there is for further observations on the relation between the number of recent corpora lutea of the same age in ovaries. They will not merely give us improved statistics as to the frequency of occurrence of double ovulation; they may serve to identify races characterized by an unusual tendency toward double ovulation—bloodlines in our population which are especially apt to be producers of twins.

MEDICAL ASPECTS OF ENDOCRINOLOGY.

By JULIUS J. HERTZ, M.D.,

NEW YORK.

ADJUNCT VISITING PHYSICIAN AND BACTERIOLOGIST, BETH ISRAEL HOSPITAL.

Our modern conception of internal secretions begins with the doctrines propounded by Claude Bernard (1857). It was not, however, until 1889 that Brown-Séquard assumed that the endocrinic glands, as the glands of internal secretions are known, supply principles to the blood which have a selective action upon certain organs, whether adjacent or remote. He suggested that interrelationship between the various cells of the economy affected by a means other than that of the nervous system. It is interesting to note that although in organic diseases in the human being extracts of animal organs were used by the Isopaths, forming a branch of homeopathy, for a good many years. Brown-Séquard at the age of 72 in experimenting upon himself with solutions of testicular extract initiated our present organotherapy. At about the same time G. Vassoli in Italy and E Gley in France showed that thyroidectomized animals could be kept alive with injections of thyroid extracts.

The endocrinic glands owe their properties to certain substances which have a remarkable power of stimulating activity in cells situated at a distance from the secretory gland itself. These substances have been called "hormones" by Professor Starling. Sir E. A. Shaefer suggested the name chaloms for substances which have an inhibitory function.

A number of classifications of the internal secretions have been attempted; one division is into: (1) Nutritive glands which include hypophysis, thyroid and thymus. (2) Regulatory and stimulating glands as the adrenals.

The changes in the skin, bones, etc., in diseases of the hypophysis and thyroid indicate plainly enough the effects upon nutrition exerted by these internal secretions.

The hormones are divided into acute and chronic. Adrenalin and the extract from the posterior lobe of the hypophysis are examples of the acute type, while thyroid extract and extract of the anterior lobe of the hypophysis are examples of the chronic type.

The hormones of the acute type are available to produce rapid and immediate results, and their actions are of short duration. This can be seen, as T. R. Elliot and B. Cannon have shown, in cases of fright or fear where adrenalin is rapidly discharged into the adrenal veins and general circulation. There is, however, a constant stream of very small quantities of these hormones passing into the circulation.

Those of the chronic type produce no apparent effect until some time has elapsed but by appropriate spacing of the doses their action may be kept up continuously for as long as necessary, even a whole life time.

The symptomatology of the organs of internal secretion depends upon: (1) Whether there is a hypo- or absent secretion; (2) whether there is a hyper-secetion; (3) the effect upon the other organs of internal secretion; (4) the fact that a hyper- and a hypo-function may be alternating.

The Thyroid Apparatus.—This consists of the thyroid and the parathyroids.

The function of the thyroid gland, which is probably the best known of all the endocrine glands is concerned; (1) with the development of the cells of the body, *i. e.*, the formation or growth of tissue which is evidenced in cretinism; and (2) with the development of the sexual organs. (3) It regulates the destruction of the albumin molecule and governs the removal of waste material resulting from incessant regeneration; the retention of such waste products causes the hard non-pitting edema of myxedema.

The thyroid gland may show an absent, diminished, or increased secretion. When we have an absence of secretion the resulting condition is called myxedema.

A slight or medium insufficiency is attended by a reactionary hyperfunction on the part of the gland, expressed by symptoms of hyperthyroidism. It may also be associated with derangement of other glands which may obscure the pure symptoms. Accordingly we classify these cases as: (1) Uncomplicated slight thyroid insufficiency without associated symptoms. (2) Slight thyroid insufficiencies with concomitant hyperthyroidism. (3) Slight thyroid insufficiencies associated with other endocrinic symptoms.

In the uncomplicated case the symptoms in each individual may be slight and few. These patients may have slight hard non-pitting edena of the upper lids, forehead, cheeks, or feet, which may be transitory and come only under the influence of worry, fatigue, or menstruation. The hair may fall out prematurely. The outer third of the eyebrow may thin out or fall out completely; this is a fairly characteristic sign. The patient may complain of coldness, especially of the feet, the temperature may be subnormal, constipation is a fairly constant symptom. Fatigue on arising in the morning but passing off during the day is sometimes noted. Obesity and dry hard skin may be present. These patients are usually short in stature. They also suffer from muscular and articular pains. They are usually apathetic and depressed and pass small quantities of urine.

In the treatment of these mild cases it is advisable to give one or two 2½ grain tablets of thyroid extract daily; or one may begin with a 1/10 of a grain t.i.d., and gradually increase the doses. In the cases of simple parenchymatous goiter of puberty and adolescence a single dose of from 2 to 5 grains of dried thyroid each day, may be of service. In cases of obesity thyroid will cause more or less decrease in weight. There are some cases in which the reduction is very marked while in others it is very slight. I believe that those cases in which the results are marked are probably related to hypothyroidism. One should begin with small doses—gr. 1/10 to ½, and not reduce the patient more than two to three pounds in a week. Those cases in which large doses are necessary are probably due to other conditions.

In hyperthyrodism the symptoms are almost the direct antithesis of those of hypothyroidism. The extreme nervous excitability, sleeplessness, tachycardia, excessive vasomotor changes and accelerated metabolism are produced in hyperthyroidism and in the condition artifically produced by the administration of an excess of thyroid extract. Even exophthalmos has occasionally been produced. Tolerance for glucose is lowered so that glycosuria may occur. The widening of the palpebral fissure with protrusion of the eyeball can be produced by stimulation of the upper end of the sympathetic ganglionic chains. The sensitiveness of the sympathetic to adrenalin is increased in excessive thyroid secretion and it is possible that some of the symptoms may be due to the former secretion.

A number of preparations for the relief of hyperthyroidism have been used, based on the principles that the blood of animals whose thyroid has been removed would do some good. Amongst these we have antithyroidin (Mœbius) hematoerythroidin (Carrion and Hallion), and thyroidectin. The efficiency of these, however has not been proven. Beebe's serum is also of negative value.

The *parathyroid glands* in the human being consist of four small bodies usually situated along the posterior border of the thyroid near the inferior thyroid arteries. They are concerned with the metabolism of calcium. When the secretion is deficient there is a loss of calcium from the tissue as shown by an increase of calcium in the urine. We know that calcium moderates the activity of the nerve cells, an excess shows itself in the form of tetany which is improved by the administration of calcium.

In infants a form of tetany is seen in which on post mortem examination, hemorrhages or traces of the same with blood pigment have been found in the parathyroids. In Escherich's clinic they were able to demonstrate hemorrhage in the parathyroids of all children under 1 year of age who during life showed hypersensibility to electric stimuli. Escherich holds the view that infantile tetany is due to disease of the parathyroids. Those cases of tetany of gastrointestinal origin and certain forms of poisoning, judging from analogy, are probably due to some influence exerted on the secretion of the parathyroid.

There are a number of conditions, such as myotonia congenita (Thomsen's disease), paralysis

agitans, and myoclonia, which are probably due to the diminished function of the parathyroids. On the other hand, myotonia periodica and paralysis myasthenica are produced by a hypersecretion or perverted function of the parathyroids.

Von Eiselsberg implanted parathyroid gland in the obdominal rectus muscle of a woman who twenty-seven years previously had her whole thyroid removed and was suffering from tetany. The graft healed in, the tetany was reduced to isolated spasms of the glottis, and the electrical stimuli became normal.

Haltead and Putnam obtained favorable results in postoperative tetany with parathyroid extract given by mouth or subcutaneous injection.

That there is an interrelation between the thyroid and the parathyroids is shown by the hypertrophy of the one on removal of the other. The administration of parathyroid extract is followed by increased intestinal peristalsis muscular contraction of the uterus, and marked diuresis. These symptoms are very similar to those following the administration of petuitrin.

Thymus.—Concerning the internal secretion of the thymus very little is known. In cases of sudden death supposedly due to enlarged thymus, the individual was probably suffering from a general lymphatic hyperplasia as shown by the skin pallor, hyperplasia of the glands of the neck, axilla, mesentery, and intestinal wall, enlarged follicles of the nasopharynx and spleen, and enlarged thymus. This organ does not seem to be essential to life.

Adrenals.—In 1855, Thomas Addison published the first account of the disease known by his name and showed the relation of disease of the adrenals to the same.

The adrenal consists of two parts, the cortex and medulla, which morphologically and histologically are entirely different.

The medulla or inner part consists of chromaffin tissue, which is a tissue composed of cells derived from nerve cells of the abdominothoracic sympathetic system, which stains brown with chrome salts, and produces a physiologically active substance called adrenalin, which is not present in the cortex. These tissues are also found at the branching of the carotids and at the branching of the aorta. Adrenalin, the active internal secretion of the chromaffin system, is a true hormone and is one of the few internal secretions of which we know the chemical composition. The adrenalin acts by stimulating the endings of the true sympathetic nerves. The secretion of the adrenalin into the blood stream is under control of the splanchnic sympathetic.

Concerning the internal secretion of the cortex or outer layer, which consists of cells which contain a lipoid substance related to cholesterin, not much is known. It forms about 90 per cent. of the gland. That the cortex of the adrenal may have some relationship with the nervous system is suggested by the fact that in encephalic children, it is absent or markedly diminished.

The functions of the adrenal, according to Swale Vincent, are: (1) It helps to maintain the muscular tone, especially of those supplied by the sympathetic. (2) It raises the blood pressure and increases the action of the heart while slowing the pulse. (3) It increases carbohydrate metabolism. (4) It destroys toxic substances produced by muscular activity. (5) It decreases fatigue.

In Graves' disease the blood content of adrenalin is increased from four to eight times. It is strange there is no increased blood pressure.

Nuesser and Wiesel suggested that conditions which demanded an increased consumption of adrenalin (and of these the most important is forced muscular exertion) may produce hypertrophic processes of the adrenal system. This increase may cause permanent vasoconstriction. They lay stress upon the fact that in chronic contracted kidneys the etiology of which is obscure, hyperplasia of the chromaffin tissue is marked.

In *Addison's disease*, the characteristic symptoms are coldness, atony, and weakness of the muscles, low blood pressure, vomiting, diarrhea, and bronzing of the skins. All the symptoms except the pigmentation can be produced by extirpation of the adrenals. The administration of extract of the adrenals does not seem to influence the disease.

It has been claimed that cats have been kept alive after extirpation of the adrenals by daily intraperitoneal injections of cholesterin. This may be tried on man by giving a 4 per cent. solution in olive oil, as much as 1 gram of cholesterin being given daily if necessary.

Adrenal extract is used a good deal in nose and throat work to prevent bleeding. It may be used in combination with local anesthetics.

It is harmful in pulmonary hemorrhage because by raising the blood pressure it drives a faster current of blood through the lung.

Adrenalin should not be used in chloroform narcosis because it may cause sudden death due to complete ventricular fibrillation.

Probably one of the greatest therapeutic uses of adrenalin in medicines is in *asthma.* One should begin with small doses, 5 to 10 minims of 1-1000 solution. The results are immediate and startling at times.

Pituitary Gland.—This consists of three distinct parts: (1) Anterior or glandular, which is derived from invagination of the buccal mucosa. (2) Posterior or nervous part, derived from the thalamencephalon midbrain. (3) Intermediary portion.

In animal experimentation Cushing showed that complete extirpation caused death, but partial extirpation of the anterior lobe is compatible with life. In some cases it leads to increased deposit of fat, polyuria, transitory glycosurea, falling of hair, reduction of sexual activity, and atrophy of the testes or ovaries. There is also acute thyroid hypertrophy. The physiological effect of extract of the posterior pituitary lobe is shown to be a prompt and marked increase in blood pressure and slowing of the pulse rate, which lasts longer but is not as marked as that following adrenalin. After a second injection there may be a reduction of blood pressure.

It causes a constriction of the coronary artery and dilatation of the renal vessels, the opposite of that produced by adrenalin. Its effect upon

the intestine, observed by Bell, is to restore peristalsis to a paralytically distended gut, whereas it has no effect on the normal.

It has a galactogogue effect, as was discovered by Ott and Scott. The diuretic action was discovered by Magnus and Schaefer. Hoskins and Means believe that the diuresis is probably due to direct stimulation of the renal cells, aided by concomitant vasodilatation in the kidneys.

Acromegaly, which was first described by P. Marie, is regarded by Benda to be due to an increase of the glandular epithelium of the anterior lobe, especially of the chromophile and eosinophile cells. In the majority of cases the tumors of acromegaly are true hypophyseal tumors—adenoma, adenocarcinoma, sarcoma. With regard to these malignant forms, Hanau and Benda found that tumors which at first sight appeared to be sarcomatous contained cells derived from the hypophyseal epithelium, and they described these tumors as hyperplastic malignant adenoma. The weight of evidence is in favor of acromegaly being a hyperpituitarism of the anterior lobe. Extirpation of tumors of the anterior lobe, as shown by Hochenegg and Cushing, has been followed by disappearance of symptoms.

That there is an interrelation between the hypophysis and other internal secretory organs, namely, the thyroid, thymus, superenals, and especially the sexual glands, has been proven beyond doubt.

Rogowitsch showed that thyroidectomy is followed by hypertrophy of hypophysis. In myxedema and subthyroid conditions there is enlargement of the hypophysis. Pinelles has shown the frequent coexistence of myxedema and acromegaly and also the similarity of many of the symptoms.

The preparations of the posterior part are sold on the market under various trade names, namely, pituitrin, hypophysin, and infundibulin. Of late pituitary extract has been used instead of adrenalin in cases of shock. It is used intravenously in doses of 7 to 15 minims, diluted. It may be used in vasomotor paralysis in typhoid fever and pneumonia. It has been recommended in the persistent vomiting in gastric crisis of Graves disease.

In the latter stages of acromegaly, where the condition of pituitary insufficiency is established, the administration of the dried whole glands, 12 grains t.i.d., has been of service.

Secretin.—When the acid chyme reaches the duodenum it stimulates the cells of the mucous membrane to produce a substance called secretin, which is absorbed into the blood and stimulates the secretion of the pancreas. Starling has shown that it is useless to administer this hormone by mouth, as it is destroyed by the gastric juice. The dry duodenal extract may be given in doses or 1 to 3 grains repeated every 20 minutes for an hour.

Pancreas.—Many theories have been advanced concerning the pancreas in relation to diabetes. I will simply narrate proven facts. (1) In animals if the entire pancreas is removed a severe form of diabetes is produced, followed in a few weeks by death. (2) When more than 1/10 of the gland is left diabetes does not ensue. When less than 1/10 is left a slight form of diabetes develops. (3) In dogs, at any rate, the action of the pancreas in relation to sugar content is specific. No other gland can take its place. (4) The external secretion has nothing to do with the characteristic disturbances of the sugar content.

This brings us down to two theories: (1) Some substance accumulates in the blood after removal of the pancreas which is detrimental to carbohydate metabolism. (2) Some substance is lacking which promotes carbohydrate metabolism.

The second theory is the one usually accepted. The pancreatic hormone has not been isolated.

There is an intimate relation between pancreas and thyroid and pituitary. Extracts of the thyroid and pituitary to a certain extent inhibit the action of the pancreas. Hyperthyroidism and hyperpituitarism are associated with diabetes. The thyroid and pituitary have an inhibitory action upon the pancreas.

64 East Eighty-sixth Street.

ORAL SEPSIS AND THE RÔLE IT PLAYS IN CERTAIN ORTHOPEDIC CONDITIONS.

By JACOB GROSSMAN, M.D.,

NEW YORK

CHIEF ORTHOPEDIC SURGEON LEBANON HOSPITAL O. P. D.; CHIEF ORTHOPEDIC SURGEON STUYVESANT POLYCLINIC; INSTRUCTOR IN ORTHOPEDICS NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE relation of focal infection to systemic disease has attracted attention within the past few years. The common sources of focal infection are usually found in the tonsils, sinuses, and in or about the teeth. Chief among the infections within or about the teeth are:

1. Infections about the teeth producing pyorrhea pockets. 2. Abscesses and necrosis in the jaw, usually at the tips of the roots, with or without sinus formation.

Bacteriology.—The mouth is the constant habitat of many bacteria, by far the largest number of which are harmless saprophytes; but there are some that possess pathogenic properties, which they display, either in the mouth or elsewhere, when suitable conditions obtain. If the care of the mouth is neglected, the number and variety of pathogenic and nonpathogenic bacteria increase. The bacterial flora of the mouth is, of course, derived chiefly from without, from the air, food, and drink; but when infective processes are active in the organs or parts communicating directly or indirectly with the mouth, the bacteria concerned in them may find their way to the oral cavity. Thus in pulmonary tuberculosis, tubercle bacilli may be deposited by the sputum in the mouth. It has been shown that the salivary glands are capable of eliminating bacteria that are circulating in the blood in cases of general sepsis; such bacteria may then appear in the saliva.

Despite the fact that the oral cavity teems with bacteria, wounds about the mouth usually heal by first intention. This is to be explained by the fact that the saliva is, after all, not a good culture medium for bacteria, although its bactericidal power is extremely weak.

Aside from the individual differences, there is a natural difference between the saliva of the submaxillary and that of the parotid gland. In most animals the first furnishes a secretion that has only a slightly deleterious action upon the bacteria; while parotid saliva is capable of inhibiting the growth of several species of organisms, mainly those of the pathogenic group, especially if the secretion is artificially stimulated. When abundantly secreted, the saliva may become sterile.

The organisms usually encountered within the mouth are divided into two main classes:

1. Protozoa, represented by the ameba, a unicellular animal organism.

2. Bacteria, unicellular vegetable organism, represented by (*a*) Cocci, such as the streptococcus, staphylococcus, pneumococcus, etc.; (*b*) Bacilii, such as the subtilis and pneumobacillus; (*c*) Spirilla, such as the spirochete.

1. Protozoa: That the ameba occurred in the mouth has been known for the past fifty years. Gross, in 1849, described the *Entamœba gingivalis;* Grassi, in 1879, described the *Entamœba dentalis*, both probably identical with the *Entamœba buccalis.* It was very doubtful at this time whether they had any etiological significance, so far as producing caries was concerned. Even at the present date there is a doubt in the minds of a great many as to whether the *Amœba buccalis* really plays the rôle in oral sepsis that is assigned to it.

A very interesting report on the results of the examination of the mouths of sixteen hundred and seventy-eight children was recently published. In one hundred and thirty children with apparently normal gums, thirty-eight or twenty-nine per cent., showed the ameba. In two hundred and ninety-two, with normal gums and decayed teeth, one hundred and nine, or thirty-seven per cent., showed the ameba. In two hundred and seventy-eight, in which there were tartar and receding gums, one hundred and eighty-two, or sixty-five per cent., showed the ameba. In two hundred and ninety-six in which the gums were spongy and bleeding, two hundred and sixty-eight, or ninety-one per cent., showed the ameba. From this analysis one would be led to believe that the amœbæ in the mouth are accidental invaders, that they are not pathogenic, and do not produce any reaction in the mouth. The reason for this conclusion is that the ameba occurs in normal mouths and that other organisms are present in diseased conditions of the mouth. Against these arguments it is said that the amebæ are found so much more frequently and in larger numbers in the lesions than in the normal mouth.

Another group of investigators claim that the ameba may be pathogenic only in connection with certain other organisms. This is borne out by the presence of other organisms in cases of infection.

One can readily appreciate how varied and complicated are the opinions regarding the status of the ameba in the production of oral infection, after reading the preceding remarks. Still there is no doubt that in a certain proportion of cases the ameba does play a very important rôle in the production of pathological lesions. Whether it produces this lesion alone or in conjunction with other orgnisms is a question which is very difficult to determine.

The following methods are very simple ones for obtaining material for examination of the ameba.

1. A warm, clean glass slide upon which a drop of physiological saline is placed; some of the material obtained from the pathological lesion is mixed with this solution. The mixture is then examined under the microscope.

2. The other method at our disposal is one in which we stain the specimen. The technique follows: In bad cases the teeth and gums are cleansed with a cotton swab dipped in fifty per cent. alcohol; with the flat end of a hard-wood sterile toothpick, the material is scraped from the margin of the gums and stroked lightly over a clean glass slide, three or four streaks being made. The smear is then fixed while still moist by dropping methyl alcohol on it. A second toothpick is used to obtain material from beneath the margin of the gums from which another smear is made and fixed in a similar manner. The smears are then stained with Giemsa's stain.

The reticulated cytoplasm of the ameba stains clear blue; the nucleus appears as a rounded or irregular mass of red granules and threads with a central light blue staining karyosome which sometimes contains a vacuole-like body. Red blood cells, leucocytes, vacuoles, and dense masses formed by undigested material are very often present.

2. *Bacteria:* Regarding the bacteria isolated in pyorrhea, opinions and the variety of organisms are numerous and varied. The general consensus of opinion, however, tends to center on one group of organisms—namely, the streptococcus-pneumococcus group.

The predominating organisms found are the *Streptococcus viridans* and *hemolyticus;* occasionally the *Bacillus fusiformis*, the *Staphylococcus aureus* and *albus, Micrococcus catarrhalis*, and a diphtheroid bacillus are isolated.

A very interesting series of findings were reported by Ulrich. In an anlysis of six hundred cases suffering from systemic disease, he found by Röntgen ray examination: eight hundred and twenty-seven teeth were abscessed, one thousand seven hundred and twenty-two were dead teeth with root canal fillings, five hundred and ninety-eight abscesses on pulpless teeth due to caries or accident. There was a total of one thousand four hundred and thirty-five abscesses. The findings of this analysis are startling as well as significant. A little over 68 per cent. of all artificially devitalized teeth were found with apical abscesses. The total number of abscesses was 83 per cent.

One hundred and fifty-nine cases had had bacteriological review: one hundred and seven cases gave *Streptococcus viridans,* and fifty-two gave *Streptococcus hemolyticus.* In another series in which he analyzed seventy-six cases clinically, he isolated the streptococcus from apical pockets.

Almost without exception the alveolar abscesses were found in devitalized teeth, devitalization having occurred either through caries with involvement of the pulp canal, or through artificial devitalization by the dental operator in preparation for crowning or bridgework. The Röntgen ray showed fillings in the pulp chamber were imperfect in the majority of cases. This, with imperfect dental asepsis, probably accounts for subsequent infections.

A striking feature of this analysis is the diversity of clinical manifestations for which streptococcal focal disease is responsible. For convenience they are classified into:

1. A rheumatoid group in which the special features of the cases consisted of rheumatoid arthritis, arthritis deformans, neuritis ,and myositis with or without cardiac involvement.

2. A cardiac vascular group exhibiting, as the main feature, heart lesions or hypertension without any appreciable rheumatoid manifestations.

3. An asthenic group closely allied to Group 1, showing joint and periarticular pains, nerve or muscle pains, but in which the main feature is one of asthenia, mild anemia, albuminuria, and occasionally myocardial weakness. Visceroptosis is a common finding in this group.

4. A gastrointestinal group exhibiting gastrointestinal ulcers, gallbladder or pancreatic symptoms, and acute enteritis.

5. A genitourinary group allied to Group 1, in having at times rheumatoid pains with renal, bladder, prostatic, or vesicular involvement.

6. A streptococcus focal infection superimposed upon tuberculosis, syphilis, primary anemia, or vice versa.

Rosenow has isolated the streptococcus not only from focal infections, but also from joints and neighboring glands in the region of the affected joints, showing the close relationship existing between focal infections and arthritis.

Goadby probably was one of the first to demonstrate the relation of dental infections to joint affections. He reported three chronic joint cases which he cured by the removal of infected teeth. He isolated an organism which he called the *Streptobacillus malæ* and which he succeeded in growing upon egg agar. He also produced disease in the joints of rabbits by inoculating these organisms, thus showing the selective action of these organisms for joint structures.

In some cases spirilla have been isolated. In these cases associated with syphilis the *Treponema pallidum* has been frequently found. Noguchi describes two varieties of organisms which he has succeeded in isolating in pyorrhea. They are both spirochetes. He calls them *Treponema mucosum* and *Treponema microdenticum*. These spirochetes develop rapidly in tissues found in a disturbed metabolic state, exerting a pyogenic action. They are not pus-producing organisms. They belong to the same class of infectious granulomata as the causative organisms of leprosy and tuberculosis.

From the foregoing one can readily appreciate the tremendous effort which is being expended in these conditions; also that the consensus of opinion centers about the streptococcus in some form or other as the commonest offender.

Symptomatology.—A, *Local*: As you all are undoubtedly familiar with the local manifestations of oral infections, I need not burden you with a description of them. Just a few words to caution you against overlooking two very common affections, namely, blind abscesses and imperfect root canal fillings. To rule out the presence of either of these conditions, a Röntgen ray picture is essential. It is a good plan where possible to *x*-ray every case subsequent to the drilling of the root canal. Were this to be accomplished one would be surprised to find how many imperfect root canal fillings really existed. It has been proved beyond a doubt that these imperfect fillings eventually give rise to a large proportion of the blind abscesses which we meet.

B, *Systemic Manifestations*: Caries of the teeth, alveolar abscess, and various forms of stomatitis being bacterial processes, often lead to disease at a distance from the mouth in one of two ways: (*a*) by the absorption of toxins and bacteria into the blood stream; (*b*) by the swallowing of pus containing toxins and bacteria.

For convenience the symptoms will be discussed under the various systems which are attacked. Only those systems which are commonly affected will be dwelt upon fully, the others will be reviewed very briefly.

1. *The Digestive System.*—The symptoms which we encounter in the gastrointestinal tract are undoubtedly the result of the enormous number of bacteria which are swallowed during and between meals. The common manifestations are dyspepsia, flatulence, indigestion, septic gastritis, and gastric and duodenal ulcers. In addition there may be gallbladder and pancreatic symptoms and also acute enteritis.

2. *The Arthritic Group.*—This group of cases has been thoroughly investigated and studied. It is these cases that the orthopedic surgeons are often called upon to treat. They generally migrate from physician to physician, from clinic to clinic, until finally they give up hopes of ever being relieved of their distressing symptoms. As a last resort they come to the orthopedist, with well advanced deformities and nervous wrecks, the result of prolonged suffering. An early diagnosis with the institution of early treatment would undoubtedly obviate the tortures and agonies which these poor unfortunates endure. The longer the diagnosis and treatment are delayed the less can we hope to do for them. The pathological changes in the various joints become progressively worse, until there is destruction of the joint structures. Those of you who have had the opportunity to observe these cases in the advanced stages can readily appreciate the impossibility of influencing the deformities so far as obtaining a cure is concerned. Take these same cases in the early stages and you have a different proposition to contend with. You can, by instituting proper treatment, prevent these incurable deformities and invalidism.

The special features of this group of cases consist of arthritis deformans, rheumatoid arthritis, neuritis, and myostitis, with or without cardiac involvement. In some cases the symptoms are so severe that the patients are bedridden. Especially is this so in the acute cases. The chronic cases are usually ambulatory, the duration of symptoms varying from a few weeks to a few years. The common sites invaded are the muscles of the neck, particularly the sternocleidomastoid; the mandibular joint, the fingers, the shoulders, the knees, and the metatarsophalangeal articulation of the big toe. This is in the order of their frequency. The disease is characterized by exacerbations and remissions, especially when of dental origin.

Weeks or months may intervene between the at-

tacks. Each exacerbation is worse than its predecessor. Fever is rarely present. The joints and the tissues about the joints usually show connective tissue hyperplasia, which eventually may lead to exostoses. One of the constant features is the partial disarticulation of the phalangeal joints of the hands and feet. Finally destruction of the articular surfaces of the joint occurs.

3. *Nervous Manifestations.*—These may manifest themselves as choreic and epileptic seizures; tic, stammering, stuttering, insomnia, mental derangement, irritability, neuralgias, and restlessness.

4. *Cardiovascular Symptoms.*—These are symptoms of endocarditis, myocarditis, and arteriosclerosis. Anemia is occasionally produced.

5. *Cutaneous Manifestations.*—These may consist of erythema, urticaria, purpura, acne, eczema, herpes and seborrhea.

6. *The Respiratory Symptoms.*—These may manifest themselves as an acute or chronic bronchitis and septic tonsillitis.

7. *Miscellaneous Manifestations.*—These may be retropharyngeal abscess, otitis media, mastoiditis, and septicemia.

From the enumeration of these systemic manifestations one can readily appreciate the many ailments that oral sepsis may be associated with. When any of these symptoms exist, especially when they resist the usual treatment, the mouth should be carefully examined for evidence of infection. Not only should an examination be made by inspection, but the Röntgen ray should be employed where possible.

Before proceeding with the treatment, the writer would like to review two conditions which are of interest to both the physician and the dentist. These conditions are "foot and mouth disease" and mercurial stomatitis.

The "foot and mouth disease" is prevalent in certain parts of New York and Pennsylvania. It is primarily a cattle disease which can be transmitted to the attendant. The organism isolated is a short Gram negative, non-motile bacillus. It was described fully by Siegel. The infection is followed by swelling and severe pain, manifesting itself in the form of an ulcerative stomatitis.

An 8 per cent. solution of zinc chloride acts almost as a specific in bringing about a quick resolution of these infected surfaces. It can be applied with a swab. A warm 2 to 3 per cent. solution of bicarbonate of soda can be recommended in conjunction. Salvarsan, in the form of a 10 per cent. solution in glycerin, has also been applied locally with a swab with satisfactory results.

Mercurial Stomatitis: Mercury, as you all undoubtedly know, is excreted in the saliva; when the resistance of the mucous membrane of the mouth is lowered the constant excretion of the mercury irritates it, in that manner opening a path for microbic infection. To obviate this, treat all foci of possible attack in the oral cavity before administering mercury; cavities should be filled, and a rigid oral hygiene should be practised.

Treatment.—The treatment will be discussed under (*a*) Prophylactic, (*b*) Curative.

A. Prophylactic: 1. Education of the Patient: Proper brushing of the teeth is very essential. Teach the patients the proper way to brush the teeth, namely, to employ a slightly moistened brush, covered with any mild powder and in a rotatory manner remove the gelatinous plaques. At night a dental cream can be used to great advantage. The last step consists of the proper use of dental floss. One must observe proper care of the brush, namely cleansing after using, and in the intervals placing in a closed tube containing alcohol or formalin; frequent renewal of the brush when the bristles become irregular and begin to fall out.

Discourage against the use of strong antiseptic mouth washes and tooth pastes. They are absolutely unnecessary in a normal mouth and in a vast majority of diseased mouths. Where there is an inflamed condition of the mucous membrane a physiological saline solution is very beneficial; where there is extreme sensitiveness of the tooth structure at the gingival margins milk of magnesia is very helpful in allaying this sensitiveness. Strong antiseptics are not necessary and at times may prove harmful.

The importance of periodic visits to the dentist should be strongly impressed upon the patients; in this way incipient caries can be detected and proper treatment instituted early.

2. Aseptic Dentistry: In an interesting report published in *The Bulletin* of the Hygienic Laboratory, Hasseltine discusses the importance of sterilizing dental instruments and not only describes in detail the best method of effectively sterilizing different instruments, but gives valuable suggestions relating to dental asepsis which, while not strictly within the subject of sterilization of instruments, are nevertheless contributory factors in improving office sanitation.

Moist heat is our best disinfecting agent for the sterilization of all metal instruments. For the destruction of nonsporebearing bacteria, moist heat at 80° C. is nearly as efficient as boiling, and for all practical purposes can be used in place of boiling.

Instruments constructed of metal, whose complicated mechanism has heretofore caused them to be considered as nonsterilizable, can be sterilized by moist heat, provided the water is removed from them by immersing in alcohol subsequent to the sterilization. Instruments, whose construction does not permit of boiling can be sterilized by chemical disinfectants.

Dentistry, which is a highly specialized branch of surgery, should use asepsis which has made possible the wonders of modern surgery, with skill and precision equal to that of surgeons. All instruments and appliances should be rendered mechanically clean by washing in water with a brush or sponge. Instruments and boilable appliances and material should be boiled in a one-quarter per cent. solution of sodium hydroxide, or submitted to 80° C. Instruments whose mechanical construction makes it difficult to remove the excess of water should be placed in 95 per cent. alcohol for ten minutes, then removed and permitted to dry.

Instruments with metal handles only should be used by dentists. Mounted stones, mirrors, nonmetallic instruments which cannot be replaced by metallic instruments should be sterilized by immersion in 5 per cent. phenol for at least sixty minutes. After using instruments, place them in a

fluid medium, preferably clean water, so as to avoid drying of infectious material and to facilitate their mechanical cleansing.

B. Curative: (*a*) Local: The importance of local treatment in pyorrhea alveolaris is well known. Many authorities claim cures by simply employing thorough local measures. The usual routine recommended follows:

(1) Careful expression of the pus from the pockets. Massage is very essential. Teach the patients to massage the gums every night, not simply to rub one side of the gum and then the other, but to squeeze in a direction from the apex of the root towards the gingival margins, pressing both sides at once. The treatment of pyorrhea pockets by evacuation of dental abscesses and curettage confers a double benefit. First, it inoculates the patient with a number of organisms, inducing an effect similar to that of an efficient vaccine, with the added advantage that the constant supply is shut off from the focus disturbed. When there are many abscesses or pockets it is important to permit three to six days to intervene between treatments in order to gain full advantage of what might be called surgical autoinoculation.

If sudden complete extirpation of all foci is practised, as for example, extraction of all teeth at once, the end result will do positive harm. If such dental foci of infection are recognized early and eliminated, systemic conditions are easily controlled. On the other hand, if not recognized early, the disease becomes firmly fixed so that the elimination of the primary focus does little in the way of repair, though it may limit further progress of the disease.

2. Thorough removal of calcareous deposits and tartar wherever found.

3. Extraction of hopeless teeth and roots.

4. Polishing of the tooth structure followed by the application to the margin of the gums of equal parts of the tincture of iodine, tincture of aconite, and chloroform, continued every other day.

(*b*) General: Vaccine therapy certainly has its place in the treatment of pyorrhea alveolaris and other oral infections. The main difficulty lies in selecting the proper vaccine and in administering the proper dose. How are we to determine which organisms to select in preparing the vaccine? Goadby and others have attempted to isolate the bacteria by a determination of the opsonic indices to the germs isolated. Of course this procedure has not proven very successful in a great many cases. Still it may prove of value in the near future. The general consensus of opinion at present is to use a mixed vaccine, that is, one made from all the organisms present in the lesion. Many prefer a sensitized vaccine, that is, a vaccine made by macerating the bacteria in a homologous immune serum; this serum being obtained from the blood of an animal immunized against the disease of the same kind as that produced by the living bacteria.

It is best to begin giving the vaccine in small doses—one-fifth to one-quarter c.c. at five to seven day intervals. Increase the dose gradually and shorten the intervals gradually. In order to obtain satisfactory results with vaccines, local measures must be instituted in addition.

As many dentists have sent me specimens of pus improperly placed upon culture media, I feel that a few words regarding the same will not be out of place. The error commonly made was the failure to spread the pus over the surface of the culture medium. A very good way to obtain a specimen is as follows: Cleanse the mouth, lightly scar the margin of the gum and tooth with a red hot metal instrument of suitable size and shape. Then heat a spear (Head's is very satisfactory) to redness, allow to cool and plunge directly through this area, retaining it there for a short time and withdrawing it straight outwards, guarding against touching any of the surrounding tissues. Spread some of this on the surface of an agar medium containing red blood cells and some of the remainder on a clean glass slide. The smear on the glass slide is for immediate examination. From the growth on the culture medium the vaccine is eventually made.

Emetine Therapy. When emetine was first introduced for the treatment of pyorrhea alveolaris, like every new drug introduced it created the erroneous impression that it was a "cure-all" for every case of pyorrhea. With this idea in mind every pyorrhea patient that presented himself to the dentist was immediately injected with emetine. Even the quack advertised extensively in the daily press, "new discovery, sure cure for pyorrhea, a boon for those who have long suffered from pyorrhea," and many other false claims. The result was self-evident. Every case injected was not cured and the vast majority of the profession and the laity were disappointed and condemned emetine.

The reason for this failure is obvious. Any one who has had any experience with emetine will agree with the writer that it is useful both as a curative agent and as an adjunct in those cases of pyorrhea alveolaris in which the *Entamœba buccalis* can be isolated, and only in those cases can results be expected. It certainly is a specific for the ameba; this has been proven time and again in the treatment of amebic dysentery.

The ameba may occur alone or in conjunction with certain bacteria. Where it occurs alone, emetine should be employed; if other organisms are present emetine and vaccine therapy should be combined. Emetine can be used locally, hypodermically, intramuscularly, or orally. Locally, a one-half of one per cent. solution of emetine hydrochloride is injected into the pockets and applied to the interdental spaces and around fixed appliances. This is to be repeated daily for five days and every other day thereafter for about ten treatments. At home the patient is advised to employ a mouth wash of the fluid extract of ipecac, two or three drops to a half tumbler of water.

Hypodermically or intramuscularly it is used in doses of one-quarter to one grain for six to eight doses.

Orally, alcresta tablets can be administered, two tablets three times daily. This is of especial value in those patients who display an idiosyncrasy for the hypodermic injections.

Mercurial Therapy. This treatment is based on the theory that mercury is a cure for all diseases of vegetable parasitic origin.

Wright and White report 100 per cent. cures in a series of sixty cases. G. H. Reed, U. S. N., reports twenty-eight cures and one improvement in a series

of twenty-nine cases. S. T. Ladd reports eight cures in a series of eight cases. All these cases were cases of pyorrhea alveolaris with or without systemic complications. There is no doubt that mercury does benefit pyorrheic patients who also are syphilitic. This is seen time and again in our daily practice.

The method, as elaborated by B. L. Wright, is a very satisfactory one. The preparation used is the succinimide of mercury. For males one grain is given deep intramuscularly, every seventh day, until the discharge of pus has disappeared and the gums have regained their normal condition and appearance. In women, one-fifth to two-fifths of a grain less than in males is given. Mercurialism of any marked degree should be met with smaller dose at succeeding injections, or if the symptoms are severe, the mercury should be discontinued until they disappear. Strict hygiene of the mouth and the teeth must be carried out while administering mercury.

Summary and Conclusions.—1. The early recognition of focal infections and removal of the same, will often obviate many incurable arthritic conditions.

2. Where arthritic symptoms fail to respond to ordinary routine treatments, focal infections should be looked for.

3. Before a diagnosis of "rheumatism" is made, one should eliminate the presence of a focal infection accompanied by arthritis.

1051 Boston Road.

FEET, AND REBUILDING BROKEN ARCHES.*

By CHARLES CROSS, M.D.,

SAN FRANCISCO.

As the result of several years' experience in the treatment of ailing and distorted feet before the great World War, and from an extensive experience gained while teaching scientific examination of feet and shoes in the Military Service of the United States (S. O., 17, Par. 3, W. D., Jan. 24, 1918) a plan of treatment to rebuild the broken

Fig. 1.—Normal feet.

arch, while the feet are in daily use during the process of rebuilding, is reported here.

The results from treatment of this common affliction have proved so satisfactory in my hands that the method is reported for the consideration of those who are interested in their feet.

The plan consists of a system of exercises on specially designed exercising appliances, massage, manipulation, mechanical force, static and dynamic

Fig. 2.—Ulcerated papilloma of the sole.

force, support, and then gradual removal of the support.

On leaving the Army and returning to civilian status a number of colleagues advised that I specialize in the treatment of feet. The insurance service, which I had rendered to various organizations for many years, and which, during the period of hostilities was looked after by my colleague, Dr. V. E. Putnam, was awaiting me, but almost all other practice had vanished. It had "gone where the woodbine twineth," where it went for so many others. It was at this period I harkened to the advice and counsel of colleagues and friends who were familiar with my work on feet. Some of them had attended my lectures and clinics and observed the methods of examination and diagnosis and the results of treatment, and some had been treated.

We held a sort of counsel of war to determine a plan of action, and how to make a drive to get back on the battle line of practice. At the suggestion of a fellow officer, Captain James H. Parkinson, of Sacramento, with whom I spent almost a year in the field, and for whose opinion on questions, ethical, gastronomic, strategic, and diplomatic, I have a deep and profound respect, an announcement was published in the *California State Journal of Medicine*, that I would "specialize in the treatment of distorted feet, by modern nonsurgical orthopedic methods." Subjoined to that announcement was a list of army officers and colleagues, who were referred to by permission.

From the number of colleagues and members of their families who have appeared for treatment as a result of that announcement, and from the number of cases referred by colleagues of this city and other parts of the State, and the cases they continue to refer, the drive was successful. From letters and words of appreciation, I believe the service is satisfactory and that there is a great demand for this specialty. (Fig. 2.)

*Read before the Surgeons of the Santa Fe R. R. Medical Department in San Francisco, September 3, 1919; and before staff of Temple Sanitarium, Temple, Tex., December 8, 1919.

At this point it may be well to add that in the Army there was very little serious foot trouble in the organizations under my command. From their words of appreciation, expressed after parting from me, I believe that every officer trained in those

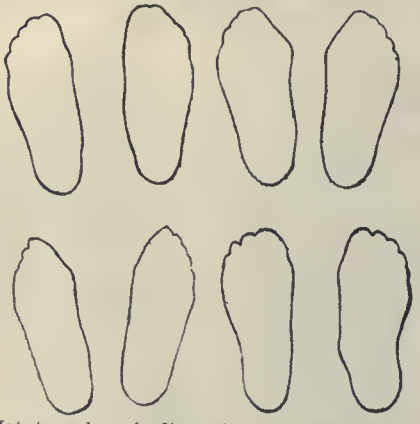

Fig. 3.—Metatarsal arch distortion, causing back, knee, and leg pains.

organizations acquired much valuable information about feet, which he was able to make use of later in his commands. The same statement applies to the men. As one of them expressed it, "Sir: You sure did kindness to me when you ordered me to take off those 6 E's and put on a pair of 9 A's; I have never had a moment's foot trouble since."

As a souvenir of Army experience I have a bound volume of the podograms and diagnosis records of the feet of almost every man who served under me, also of many officers who volunteered to act as subjects for clinical lectures given to their organizations.

While in the Army, and in the field, when a man of my command appeared complaining of pain below the diaphragm, unless the cause was visible, or the symptoms very pronounced to the contrary, his feet were examined. In about ninety per cent. of the cases the cause of the pain was located in the feet, and a little treatment directed to the offending area saved a man for duty and relieved the hospital of a patient, and in many cases a broken arch was prevented.

Rebuilding Broken Arches.—In rebuilding broken arches the aim of this system of treatment is to reconstruct the arch and so strengthen the foot that it will stand ordinary usage, without the aid of arch support. Arch supports at best are but splints and should be used only as such. Constantly wearing any kind of a rigid splint weakens the muscles because free action is restricted. This is especially true when metal splints, in the form of arch supports, are worn under the feet, and the general results from their use is a degree of atrophy of some muscles and weakening of others.

The process of rebuilding broken arches by this system aims to follow the same lines followed by engineers to replace a bridge span, or a house foundation, that is out of alignment. A careful drawing is made of the foot and this is surveyed to determine the degree of distortion or displacement. Then begins a system whereby the broken arch is blocked up or strapped up by degrees, as rapidly as possible with comfort, until normal function is restored.

In the process of rebuilding it is sometimes necessary to apply a considerable force to replace bones which have long been distorted. In some cases an anesthetic may be required to bring about the necessary relaxation to permit replacement. Following the manipulation, the feet are strapped in the new position and again put into service as soon as the anasthetic wears off. If properly handled there is little or no distress following this procedure. (Fig. 4.)

After the desired elevation is reached the foot is maintained at that point until the process of adjustment and strengthening is completed, and is kept in that position until it is thought advisable to begin the process of "building down" or removing the temporary support. This part of the treatment is very important and requires much care. Bit by bit the foot structure is tested, the supports are removed by degrees and the foot left to perform its normal functions.

The degree of recovery which can be expected from this system of treatment, and the duration of treatment, depend upon several factors. The factors are: the degree of distortion, the duration of the ailment, the patient's physical condition, and the ability of the patient's muscles to "come back"; also a correct diagnosis and the patient's intelligent co-operation in the treatment. In some cases reconstruction occurs in a very few weeks, while in others a much longer time is required. In the cases which cannot "come back," so as to eliminate the use of supports, it is usually possible to restore normal function, with increased comfort and increased efficiency, which follows from the beginning of treatment. Another of the very acceptable features of this system of treatment is that clumsy and freak shoes are not a part of it. Any shoe the patient selects which is long enough and wide enough can be worn.

Many patients come wearing metal arches. In such cases it is necessary to ascertain the degree of muscle weakening, or atrophy, which has followed the use of such rigid splint material. For this purpose a temporary pattern pad is used. On this pad, after it has been worn a few days, is registered the pressure points which indicate what

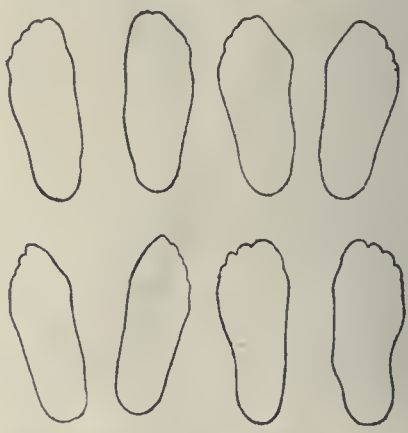

Fig. 4.—Variations in outline caused by longitudinal and metatarsal arch distortions.

part of the foot carries the greatest portion of the burden and what part carries no burden.

From this it is possible to estimate where elevation is required and to what degree. In my experience this plan is far superior to the mucky,

messy, sloppy process of the plaster-of-Paris cast. It also appears more accurate in that it is a record of the foot in action, which is not the case when the plaster cast is used. Patients who have worn metal arch supports require longer treatment, but the results are generally satisfactory.

Most patients who present themselves for treatment, at this time, have been the rounds; some to orthopedists, some to chiropodists, some to shoe clerks, and others to family physicians. From the amount of hardware that some of them bring in, it seems that they have been referred to blacksmiths, also. For this there is no criticism. As it is my aim to do the very best I can, I give the same credit to others. But when it is more generally known how easy it is to prevent broken arches, when the feet begin to ail, also repair them when they are beginning to break, the great mass of chronic sufferers from this affliction will be lessened.

Specialists to Treat Feet.—There are prominent specialists for various parts of the anatomy, so why not specialists for that part of the anatomy which everybody sees, which everybody needs, which everybody uses every day in the year—the feet?

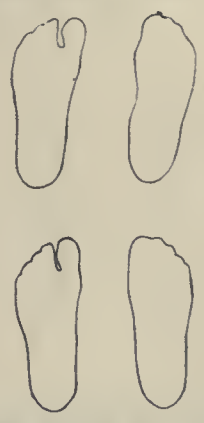

FIG. 5.—Changes in the right foot; in the upper figure at the beginning of treatment; the lower figure shows complete recovery three weeks later.

While lecturing at one of the Army camps, I was requested to give a special course of lectures to Medical Officers, with the view of their specializing in this branch of practice. Most of the officers who were enrolled for that course have returned to civil practice and are located in different parts of the country. If any of them will communicate with me, I will arrange to continue the course of instruction.

The feet are such very important parts of the human economy that the unskilled should not be permitted to tamper with them, nor with other human ailments. This is not the claim of a medical trust. It is just plain, ordinary, uncommon common sense. The man who has an automobile to be repaired does not seek a watchmaker, nor a stone-cutter. He seeks the skilled mechanic, one who knows the position and purpose of each intricate part. The importance and ability to render expert and skilled service is recognized. Is as much intelligence displayed when the delicate and efficiency-maintaining human machinery of locomotion, the feet, are concerned? Not so, and especially is this true when the ailment begins. Here the business man, careful about every detail of his complicated enterprise, is likely to go the rounds mentioned above and patronize the blacksmith, or other incompetents, when he himself, a member of his family, or an employee develops evidence of ailing feet.

Such procedure only prolongs their suffering, makes it worse, and necessitates longer treatment when they finally reach the right place. As a specialist in this branch of practice I should not complain. But I do complain, because it entails a useless economic waste. To recognize promptly and positively, and make a correct diagnosis of the most insidious and common ailment of the feet, requires a skilled diagnostician who understands the use of scientific methods of examination and diagnosis, and who also understands feet.

With the aid of an outline tracing of the feet, properly made with a podograph, and a notation on the tracing of the location of visible blemishes, and a record of the symptoms complained of or elicited, I believe it is possible to assist the attending physician to make an accurate estimate of the degree of distortion and a correct diagnosis without seeing the patient. That statement is made because of successes from surveying tracings which have been sent in by colleagues, and aiding them in the diagnosis and treatment of cases remotely situated. (Figs. 3, 4, 5.)

Broken arches can and should be prevented. The earlier the diagnosis, and the more prompt the treatment, the better the result in all foot ailments. If they do not come in time to be prevented the plan described above has given such satisfactory results that it is recommended.

There are applicable to every individual case details which cannot very well be covered in a printed article. Something definite may be added by a review of the symptoms presented. For that reason, and in the hope of being able to aid in the care of cases remotely situated, correspondence is invited on any subject pertaining to feet.

This report is confined to rebuilding distorted longitudinal arches. Rebuilding the anterior metatarsal arch and preventing Morton's toe, Golfer's foot, and Automobile foot, will be made the subject of another paper.

4263 CALIFORNIA STREET.

SACCHARIN.

BY STEPHEN H. BLODGETT, M.D.,

BOSTON, MASS.

THERE has been so much written in the lay press during the past year or two concerning the effects of saccharin that I think it may be of interest and also useful to record some experiments I made several years ago.

Saccharin is present in a Brazilian plant, but as this source is so very limited that the cost to produce it in practical amounts would be enormous, therefore for commercial use it has been manufactured from toluol. By some writers it is classed as a drug, but as far as experiments show, it has no effect *per se* on the human body. Therefore it can only be considered as a condiment, in the same category as salt, pepper, ginger, etc., and its particular use is to make palatable, food which otherwise would be unpalatable.

Where sugar is contraindicated, or where its use is impracticable on account of scarcity or high price, saccharin may be used as a perfect substitute for sugar to produce the sweet taste desired.

And right here I would like to suggest a thought about the use of sugar. The per capita use of sugar (a most concentrated carbohydrate) in this country has increased from less than 20 lbs. per year in 1864 to over 90 lbs. per year at present, and during the past fifteen years cases of so-called diabetes, or inability properly to take care in the system of the amount of carbohydrate ingested, have very markedly increased. Whether this is partly the result of the large increase in the amount of concentrated carbohydrate (sugar) ingested, cannot as yet be answered with certainty, but many of the men who are experimenting in this particular field are already feeling that if the per capita ingestion of sugar was somewhat lessened, it would be to the advantage of the average person. And this brings before us the question: How, if advisable or necessary to lessen the intake of carbohydrate, can we satisfy the rapidly increasing taste of the average person for sweets, and yet limit the amount of carbohydrate ingested?

In 1907, as very little of a practical nature was known about the use of saccharin as a sweetener of food, I employed a trained nurse to make experiments and work out definite formulas for the substitution of saccharin in the place of sugar as a sweetener of various kinds of food. Then, that I might learn the effect of its use on the normal adult, I arranged with two men that they should take such amounts of saccharin daily as I chose. The men were of ordinary physique: A weighed 144 lbs., and was 50 years old. B weighed 129 lbs., and was 42 years old. Both had been well for years. A was a clerk, being on his feet from 8 A.M. until 5:30 P.M., and B a bookkeeper, sitting at a desk all day. However, B walked to his work every morning, about one mile, and usually walked home in the late afternoon.

The lungs and heart of each were normal, and the examination of the urine of each showed no abnormality. As far as could be discovered, they were just ordinary average human beings, both men working indoors, one on his feet nearly the entire day, and the other sitting during the entire day, with only a one mile walk in the morning, and sometimes (probably two-thirds of the year) also in the evening.

They were allowed no sugar or food containing sugar (as such) during the course of the experiment. The saccharin used was the "soluble saccharin" so-called, the sodium salt. The subjects did not know what was being used to sweeten their food during the early part of the experiment.

I saw the men on an average of four to five times a week, and would ask them as to any symptoms, taste of the food, appetite, feelings as regards energy and zest for work, etc., headache, sour stomach, or "heartburn," so-called. They ate two meals each day at the table with the trained nurse, and were thus under her observation more particularly as to appetite, etc.

The amount of saccharin was increased and decreased without their knowledge. The urine was examined at least once a week, and always the second day after the amount of saccharin had been increased, in order to make sure that they were taking the amount ordered.

The nurse prepared the articles of food and drink that contained the saccharic, and it was her province to see that the amount of saccharin ordered was taken daily.

The feces, sweat, etc., were not examined, as I felt that if excessive amounts were given to ordinary human beings during an entire year, we would be able to discover by ordinary methods of examination any deleterious effects which might be produced.

The amounts given daily to each subject, also the average weight during the two week period, are recorded below:

Period.	A		B	
	Daily Amount, Gr.	Weight.	Daily Amount, Gr.	Weight.
1st and 2d week....	1.5	144	1.5	129
3d and 4th weeks....	4.5	144	4.5	128

51st and 52d weeks...	23.0	146	23.0	127

*During eighth week bitter taste following some meals; disappeared wit hin one hour.
†Twenty-fourth week persistent bitter taste; lasted one week.
‡Diarrhea.

They were weighed twice each week, and the weight given is the average of the weights for the two weeks period given in even pounds:

Weight of A, maximum.....147 lbs.
minimum.....142 lbs.
Weight of B, maximum.....129 lbs.
minimum.....123 lbs.
(Except diarrhea 3 days, weight 118 lbs.)

There were many times when they told me that some particular article of food was bitter, but only in the case of B was there a persisitent bitter taste. This occurred during the 24th week, after he had taken 23 gr. daily for nearly four weeks. He described the taste as a bitter and metallic taste, which was constantly present. All saccharin was stopped and after eight days the bitter taste had disappeared.

Subject A had a "cold" twice during the course of the experiment, lasting five days and thirteen days respectively.

Subject B had a diarrhea lasting three days, at the end of which time his weight had dropped from 125 lbs. to 118 lbs.; from this it increased and in five days was 123 lbs.

With the exceptions above noted, there did not occur during the year that they were under con-

stant supervision, or during the following year, when they were seen as often at least as once a week, any untoward symptoms, and of course the colds and the slight diarrhea could not be attributed to any action of the saccharin, because the saccharin was not discontinued, and the colds and diarrhea got well.

It was noticed that when the daily amount of saccharin was much over 5 to 7 grs., some of the articles of food in which saccharin had been used would have a bitter taste, and with the consequent result that if the men had been left to their own inclinations, they would not have partaken of any more of that particular article of food. This agreed with my experience in regard to the use of saccharin as the sole sweetener of the food of diabetics, which was that where saccharin was the sole sweetener and the person was allowed to use as much as he wished, the daily consumption usually amounted to 5 grs. or less.

In talking with patients who have been compelled to use saccharin as a sweetener for all food and drink (and allowed unrestricted amounts) for in some cases twenty years, I find there is no tendency to increase gradually the amount of saccharin used daily. This has seemed strange to me when I realized how the per capita consumption of sugar has increased during the past twenty years.

Following this experiment, I gave to a bull dog (weight 51 lbs.) before his morning and evening meal 15 gr. soluble saccharin dissolved in 2 oz. water (30 grs. saccharin daily). This was given by means of a syringe with a rubber tube on the end and the tube placed inside his lips, the lips being held tightly together and the head raised. As soon as the dog had swallowed this, he was given his meal, which consisted as had been the custom for years, of meat scraps, bread scraps, and oatmeal from the table, and enough added dog biscuit to give him a sufficient quantity. The dog at first rebelled against the injection, but before two weeks, he became so accustomed to it that he expected to receive the saccharin injection into his mouth before he was given his food, and when I took up the syringe he would run to me, wagging his tail, and as soon as it was over, he would begin to dance about, expecting his breakfast or supper.

After thirty-five days of this, as there was no diminution as regards his appetite, and no other symptom that I could discover, I stopped the experiment.

Now just a few words as regards the continuous use of saccharin by human beings. A former patient who, because of the presence of large amounts of sugar in the urine, was put on a carbohydrate restricted diet, but allowed to use saccharin without restriction, has been using it continuously since 1896. He uses on an average between 7 and 8 grains a day, and never has he had any symptom that could be attributed to saccharin, and I have among my records several cases where the patient has been placed on a carbohydrate restricted diet, but allowed the unrestricted use of saccharin for over fifteen years without any untoward results.

My experience in the treatment of diabetes during the past twenty-one years is that a too restricted or badly balanced diet may cause headache, heartburn, etc., but when the diet is properly regulated, these symptoms disappear, and saccharin, by making more articles of food palatable and by satisfying the patient's craving for something sweet, allows us to add needed articles to his diet, and this makes possible a properly balanced diet and also makes the diet palatable, and the headache, heartburn, etc. promptly disappear.

520 Beacon Street.

THE MEASURES OF INTELLIGENCE DIAGNOSTICALLY REMEASURED.

By J. VICTOR HABERMAN, A.B., M.D., M.S.D.,

NEW YORK.

(*Concluded from page* 475.)

Test (e)—repeating of a story: This test is one for the *context* of memorial matter, or "logical memory," as contradistinguished from verbatim recall. It also serves as a test of report (or fidelity of memory) and so for deferred recall.*

Binet originally had a "report-test" in the *eighth* and *ninth* years. This was the account of the fire, which was *to be read by the child,* who then had to tell all it remembered. The passage was divided into so many remembrances or "details," of which two were required *at eight* and six *at nine.* Binet dropped the test later, as did also Goddard; nor does Yerkes use it. Terman, however, makes a plea for it and retains it in the *tenth* year, requiring at least eight "memories," and allowing no more than two errors.

This test given in the above manner is partly a test of reading ability, partly of attention—or grasp-span (and if poorly done, may mean two very different things—poor reading ability or poor attention-span). Save that this passage was read by the child itself, the test is not dissimlar to the sentence test just discussed—in which the sentences extended beyond the attention-span for verbatim recall; and no little of what we noted in our comment on the foregoing could be applied here. In Binet's test and also in the form Terman employs it, exact word for word recall is not expected, slight changes in phraseology and even slight substitutions, being permitted. Nevertheless, the individual items or "memories" into which the passage is divided are required.

Bobertag retains the test, but does not speak favorably of it, and points out that the scoring and evaluating of the performance is very difficult, if not problematical. Much, he says, depends upon the kind of passage used and its length, and what one wishes to designate as "single memories." Bobertag makes a very interesting suggestion for its change, proposing that the passage (and he substitutes one of his own choosing) be divided, not into its individual ideas, or detailed memories, but rather into its contextual elements (*Einheiten*), the rating to be computed on these. The seven elements (instead of twenty-five single memories) of the story employed are as follows (and the story itself may be intimated from these elements without giving it in detail):

*The same story is also again used under Combination in testing the child's "grasping the *point* of a story."

1. There was a man and a child.
2. The man showed the child the Christmas tree (went around the tree with him).
3. He carried a lamp.
4. He (tripped and) fell.
5. A fire started (they were both burned).
6. The neighbors put it out.
7. The man and child were taken to the hospital (and died).

The story test as we employ it eliminates the reading element, and so remains wholly one of *recall for context of a story heard.* After presenting it to the child but once, one requests its repetition: "Now tell me the story again."

One would think that this test might have very real value, for the hearing and recounting of stories is the very commonest occurrence in childhood. Yet one must conclude, judging from the work of many experimenters (see the general summary of these given by Whipple,[9]) that the test in this form* has but little significance for us, partly because of the difficulty in evaluating and rating the performance, partly because of the wide individual variations possible, and finally, because it correlates but indifferently ("unexpectedly low" in several experiments) with intelligence as guaged by class standing or in collation with other separate subjects. It has value, however, as a qualitative test, but even as such, the Meumann test of building a story out of a series of "stimulus" words is much superior. (See under Combination.) On the other hand, Goddard found the test to be especially good in separating idiocy from milder feeblemindedness.

The test might be used as a supplement to the sentence test, and then after a period—and this is our only reason for telling the story at this point—brought up again by having the subject relate the story to note his fidelity of report (under test (i)).

The following story (again used under Combination, (f) may be employed:

"Once upon a time there was a little girl who had lost her mother and father, and was all alone, and so poor that she had nothing more than the clothes she wore and a piece of bread in her hand. But she was a very good and pious child, and thus wandered forth into the world without any fear. Soon she met a poor old man who was very, very hungry, and begged for food; so she gave him her piece of bread and went on. Soon after this a little child came along shivering, with nothing on, and who asked for clothes; thereupon our good little girl gave her own clothes to the child and continued on her way, herself now trembling with cold. And so, finally, when night came, she had nothing at all left, having given everything away; then suddenly the stars began to fall from Heaven, and as she picked them up, she found they were beautiful, bright dollars, and as many as she wanted."

Test (f)—carrying out of commissions: This test is for the most part a memory test. Thus Bobertag comments, "If one has listened attentively, then the rest is but memory-matter." However, there is something in this test beside, namely, an element of action, of practical doing, which lends particular interest to it. Binet pointed out the fact that retarded children, though they can be trusted to perform one commission, cannot be given several at the same time. The reason for this seems to me to be found in their inability to defer recall (cf. test (b)). In this test two commissions must be deferred and borne in mind while attention busies itself with another performance, and then the third commission be still deferred until the second is accomplished. It has somewhat similar significance as Ziehen's test of deferred recall, and, indeed, might even be combined with that test, the three actual commissions being carried out instead of the "make-believe" ones (in which case the test, however, becomes more difficult).

It seems to us a good test and one that might be serviceable in spotting defect. It is not absolutely *defect diagnostic,* however, for there are defective individuals, who will mechanically carry out commissions; on the other hand, disturbed attention, even where there is normal intelligence, might jeopardize the outcome. The test, when accomplished, therefore is not especially *intelligence diagnostic.* Nor is its achievement decisive of a special age level. Binet at first had the test in the sixth year, but in the revision placed it in the seventh. Goddard gives it in the sixth year, while both Terman and Bobertag think it properly placed in the fifth. Terman thinks it an excellent test; Bobertag, on the other hand, scarcely thinks well of it, believing the intelligence but little involved in its accomplishment, and declaring the test easier for feebleminded than the "patience" test in the fifth year. Yerkes does not employ it at all.

Terman expresses the opinion that a test of this same type, though more difficult, ought to be developed for some later age level. There is no reason, if this test is employed, why it should not be given at *every* age level. Indeed, this is one of the greatest failings of the Binet method (and Terman's and the various revisions) that a certain type of test is given at one age level and then never again or but once again applied, or one function tested twice in the same age level and entirely ignored at another.* We give the test, therefore, at each age level,† and believe that five commissions may be asked in the ninth,, certainly in the tenth, year (though this has not yet been standardized on any special group). We give the commissions in the usual way: "Do you see this key (pencil)? Go put it on that chair (indicating the chair), then shut the door (in our office the command of opening the door is more feasible, as this is usually closed—but opening is more difficult than closing, necessitates more work and attention), and after that bring me the box which you see over there (point clearly to it). Now, remember, first put the key on the chair, then open the door, and then bring me the box. Now, go ahead." To this series one might add one commission when giving the test in the seventh or eighth years (namely, straightening a pillow lying on the couch) and two commissions in the ninth and tenth (the one just men-

i.e. an immediate memory test for context of ideas. The *story-test* has very great value, on the other hand, when it comes to probing the child's ability to grasp the "point" or theme of a story, the ability to see the moral or motive underlying the context. This, however, belongs to Combinational ability, and is taken up under that caption. (See test-sheet.)

*For a fuller discussion of this point see Nos. 2 and 4.

†The test is also given at each age level by Treves e Saffiotti.[10]

tioned, and that of getting the Dictionary from a group of books on a nearby shelf).

Test (g)—Copies a square, triangle, diamond, etc.: In this, immediate *visual* memory is tested, more exactly, visual memory of simple outline-figures. The figures employed are the square, triangle, diamond and a more complicated figure suggested by Ziehen.

Binet's tests of copying the square and diamond were not memory tests, but tests of execution, the child having the model placed before it. The drawing was carried out with pen and ink, and but a minute was allowed for its completion. Copying the square was required *at five*, the diamond *at seven*. In 1911 the latter test was placed in the *sixth year*. Binet's drawing designs test in the *tenth year*, however, is a memory test. Terman placed the test of drawing the square in the *fourth year*, and more sensibly had the child use a pencil. A crayon at four would seem still more logical. Indeed, we do not see why any of the drawing tests should be carried out with pen and ink, as such are not employed for drawing lessons in the schools. Copying the diamond (but using pen and ink) Terman keeps in the *seventh year*, the model, in both tests, being placed before the child, who is told to make one just like the one shown.

Terman *at four* allows three tests with the square, and requires one satisfactory execution. Of the diamond test *at seven*, two of three trials must be satisfactory. Terman intimates that the test would be warranted at six only if pencil were used and one success required in three trials. Binet at five gives but one trial. Drawing the diamond, he states, is accomplished by but one-half at six years (why then place it in the sixth year?), and even a fifth fail at seven. Goddard keeps the tests respectively at five and seven, also permitting but one trial. Kuhlman at five asks two trials of three. Bobertag gives the test in Binet's fashion; advises, however, that one ask the child's criticism of its own accomplishment. A child's satisfaction with a poor drawing augurs badly, while dissatisfaction with a fair, even if not entirely good, drawing, augurs propitiously for the child's intelligence. Only 32 per cent. of his six, and but 61 per cent. of his seven-year-olds passed. (An *eight-year* test, therefore.) The intelligence factors in this test, Bobertag holds, are: 1. The drawing must be comprehended and firmly held in mind. 2. The execution must be controlled through (observance of) the original.

Bobertag in this test made an interesting observation, which may be mentioned here (we will come upon it again as a consequential factor, but in a different connection, and on the authority of another observer—under comprehension of pictures), which makes it evident that a child's mental associations "abstracted" from geometric figures must be rather inexact and often faulty. He asked his children what the drawing (square) was, *i.e.* represented, and the answers were: Window, picture, letter, room, card, circle, "round," a four-cornered circle; and as to the diamond, it was a star, cross, zig-zag, "slanting," etc.

The test of drawing the triangles—in the manner of Binet—was suggested by Saffiotti (l.c.) and placed by him in the sixth year.

Meumann used these drawing tests as *memory tests* ("mit Abdecken"), keeping them, however, in the same age levels. Ziehen also uses drawing tests as memory tests, employing various angles, and more complicated figures (shown below). He exposes the figures 15 seconds,* than covers them, waiting 15 seconds, and then has the child draw what it has seen. Ziehen, however, has not standardized his drawings for exact ages.

Ziehen's test figure.

Trying out the Ziehen drawing (as a memory test) on sixty children between the ages of 8.5 and 14, at one of our best schools, and comparing the technical execution with the teacher's class rating of the individual children, one was led to infer that, on the whole, there was no definite correlation between drawing ability and grades of intelligence. Some of the best students were execrable draughtsmen, while some of the very poor ones made an excellent showing. The very poorest students of the class, however, did badly in the execution.† It is probable enough that talent is a real factor in drawing, and such talent and intelligence show no especial correlation. In fact, it is astounding, all in all, how little our powers of graphic reproduction are developed—though drawing was one of the earliest practiced of the arts—how primitive our ability, for instance, whether as child or adult, whether as cultured or uncultured, to put on paper even in the crudest form, even in outline, a recognizable likeness of the familiar memory of horse, cat, dog, pig, etc.

The majority of the children made their drawings smaller than one would have expected. The size of the drawing did not in any way correlate with the performance of the test or the intelligence (class standing) of the child.

As to giving this test as a memory test, there seems no reason why a combination of lines should not be definitely retained in memory just as well as a combination of sounds (words and sentences), and no reason why memory for forms should not be included in mental tests, as well as memory for familiar colors, sounds, etc. In determining corre-

*Instead of 10 seconds, as Binet does, Yerkes also allows 15 seconds for the drawing of design test.

†Through the kindness of Miss Gillingham, one of the principals and a teacher in the art department of the school, I was given the drawing class rating and I.Q. of a group of 19 children, the result of which paralleled my own findings testing with the Ziehen drawing. The eight children with the highest I.Q., and 7 with the lowest, rated as follows (rating with "superior," "above average," "average," "below average," "poor"):

I.Q.	Class Rating	I.Q	Rating
130	Above average	117	Below average
130	Above average	114	Superior
131	Above average	112	Average
131	Below average	107	Poor
133	Superior	106	Average
139	Below average	100	Above average
142	Superior	*99*	*Superior*
142	*Poor*		

I was also told that many of the more intelligent children evidenced motor-incoordination as seen in poor penmanship.

Meumann,[15] commenting upon such incoordination—more strictly on manual dexterity in drawing—says

lations with intelligence, however, we must first decide just which functions are herein exercised.

To this purpose we may advantageously draw upon the conclusions of some highly interesting studies of Meumann with tests of *drawing from memory, i. e.,* drawing objects or designs exposed a brief time and then shut out from view. Meumann (No. 15, Vol. III, p. 719-760) first pondered the question, "What are the causes of poor drawing in individuals who draw badly?" Of course, in some observational powers are defective—their vision does not *see;* in others manual dexterity is wanting—their hands will not, cannot execute. Yet there are such who, in spite of good observing ability and motor adroitness, nevertheless cannot draw. A series of test-persons were thereupon requested to sketch from memory some object quite familiar to them. After this was done the object had to be carefully described. In the event of this falling out poorly or proving impossible, a picture of the object was placed before the test-person, who then had to describe the picture. From this series of procedures one could easily determine whether the poor draughtsmanship was due to shortcomings in seeing, understanding, or ideo-motor elements. Meumann concluded from his findings (and this should be remembered in connection with our later tests of *fidelity* of memory) that most people see things very imperfectly indeed. Many prominent details are even overlooked, though the thing pass before their eyes a thousand times (a coin, a stamp, their pocketbook, a landscape, etc.). Their *seeing* is not an *analyzing* and *remembering* seeing, not a seeing intent upon really recalling form and color of things, but merely a seeing, chiefly for the purpose of either again *recognizing* things, or in order to become acquainted with their practical traits, facts indispensable in everyday life, or in order to derive an indefinite æsthetic pleasure from them. And people haven't the slightest idea of the vagueness of their observations of forms and colors.

In some this vagueness is due to the fact that the intention of observing analytically, *i.e., analytical seeing,* has not been awakened in them. In others such intention has been developed, but they *cannot* observe correctly. The first group may be trained and with a little practice do exceptionally well in *describing* the thing to be drawn—hence, show good analytical observation and memory of the observed—yet, nevertheless, cannot draw it. Here the ideo-motor elements need not be defective.

Meumann finally summarizes the various possibilities of causes for disability in drawing from memory as follows:

1. The intention of analytical seeing and recalling of forms and colors of things may not have been awakened.

2. In cases where such intention has been awakened, the ability to see analytically may nevertheless prove difficult (be defective).

3. The optic memory-pictures may be defective (especially show presence of gaps and indistinctness) and be particularly defective for form and color. There may also be defect of memory for spacial relations.

4. There may be an inability to hold (with the attention) the optic memory-picture, especially during the act of drawing itself.

5. There may be defective co-ordination between the optic memory-pictures and the drawing-*movements.*

6. Disturbances may be caused by the incongruence noticed by the individual, between the actual drawing he is making and the intentions (differing so from the drawing being constructed) hovering before his eyes.

7. In certain drawings (especially such of tridimentional type—in perspective) we need the knowledge of schemata of construction. The lack of such acquired drawing-schemata may be the cause of failure.

8. There may be lack of understanding for the projection of tridimentional space on a plain.

9. There may be defect of manual adroitness or skill.*

10. In higher tasks there also comes into account the absence of *artistic sense.*

Of these Meumann surmises that 2, 3, 4, and 5 are matters of innate endowment-defects. The remaining causes depend upon lack of training, although 8 appears to occur also as an innate defect.

On the other hand, individuals are found who have no distinct memory-pictures and nevertheless draw well. Of such there are two types: individuals of the one depend upon their knowledge and *reflection*: such think, "How must this thing have been?" and supplement their defective or fragmentary memories with analogies and scientific reflection anent the make up of things—and so work out their drawings tolerably well. Individuals of the other type have likewise imperfect memory-pictures, but happen to possess a highly developed ideo-motor co-ordination and facility of hand, and eke out such memory-images as they may have to exceptional advantage.

The results of still another series of investigations (of Meumann, together with Albin) are of importance for us. Simple drawings yet of quite unusual design, were presented to a group of trained adults, and 45 children of the Real-school ranging from 9 to 18. The drawings were such as had no resemblance or reminders of anything seen by the test-person before (were chosen with this intent, not to call up former memory-images), and when exposed, had to be *fixed* (the gaze being riv-

*To test this have the child (a) draw several parallel lines, (b) a straight line from one point to another, (c) a horizontal line from right to left, then from left to right, (d) a vertical line from above down, then from below up, (e) a line from corner to corner, first from below up, then from above down, (f) a set of curves, one tangent to a horizontal line, one tangent to a vertical, etc.

---

that such dexterity and drawing ability do not cover one another. However, the especially poor draughtsman has often also an "uncertain" hand, and vice versa, the best draughtsmen give a good showing in dexterity; but it also happens that wholly untalented draughtsmen at times have very great manual adroitness, and good draughtsmen a mediocre ability. (Vol. III, p. 754.)

As to correlations between intelligence, as rated by the teacher, and drawing ability, Meumann (p. 742) found that the better endowed children on an average showed better accomplishment in drawing than the unendowed. Kerschensteiner,[20] in his study of the drawings of 300,000 school children, concluded that children with good intelligence regularly have good ability for graphic expression, but that the reverse was not true.

eted to a certain point marked with an asterisk) in order not to allow moving of the eyes, and a *sizing up* of the design. The exposure lasted 10 seconds, whereupon the design was immediately drawn. The point at issue was to suppress all construing seeing, and have the test-person draw the design as blankly noted, *i.e., as merely perceived.* The task proved impossible, and, in fact, for all ages and all degrees of endowment. The skilled engineer and architect succeeded no better than the child of 9. Only on repeated exposures, only as the design began to be *grasped* and *understood,* or as Meumann puts it, only when *analytical, construing seeing* took place, was the task accomplished. To copy something from memory (something first seen, but then withdrawn or no longer within vision), therefore one must first have *en-scoped* it, grasped the idea—and this is accomplished through *analytical and construing observation.*

And now to return again to our test problem: After consideration of the above, it seems that we might apply our drawing tests in a manner that would make them more *intelligence-diagnostic* than as hitherto given. Thus one might offer the test in three parts (1), *as a memory test,* the child looking at the model 15 seconds, then after this has been removed, drawing it wholly from memory*†; (2) *as a test of execution,* the child drawing the figure again with the model before it (one telling the child to look carefully at the model and copy it exactly); (3), the model is again removed and the child given its two drawings and asked if they are good or not, and to judge which is the better and why (*autocriticism*). At this point the original may again be shown and the child asked if it still maintains its criticism, or wishes to alter it or amplify. A lead pencil is used for all the drawings. Especial dexterity, that is, the graphic correctness of the execution itself, must not be accounted a factor in the test under (1) and (2); one will expect the child merely to get the *idea* of the form to be drawn, lines, angles, position, *i.e.* the general *build* of the models shown. Under (3), however, the child's opinion of the execution as such also comes into play.

Binet's copying of designs (two complicated designs) in the *tenth year* is given by him wholly as a memory test. Ten seconds we think is too brief a time of exposure for this test, and the instruction, "Examine both drawings carefully and remember that you have only ten seconds, and ten seconds is a short time," etc., which Binet gives, most disconcerting, for it may produce a panicky feeling or confusion in the sensitive child, and lead to inhibition. The test is pronounced passed if one drawing is correctly reproduced, and the other half-correctly.‡ In the one drawing the inner rectangle must be off center to count as all correct, only half credit being given if this is not so (Terman).

As to the evaluation of Binet's test, this does not appear simple. There seems to be a difference in the performance (less errors) if the design (a) is placed to the right of (b), as Terman has it, instead of to the left, as Binet placed it (Terman). Likewise, according to whether the grading is rigid or lenient, Terman notes, it may be placed in the tenth or eleventh year. Levistre and Morlé, however, placed it in the twelfth.*

Miss Town, in her authorized translation of the Binet tests, speaks of one of these designs as a "prism." Surely this is not meant to be a drawing in *perspective.* If so, then its accomplishment ought to be expected only at a more advanced age, for according to Meumann (No. 15, p. 286), Kerschensteiner (l.c.), and the exceedingly interesting studies of Schrenk,[21] knowledge of perspective in a drawing develops late indeed. The first, testing sixty children of the ages of 13 to 14, found but seven had any idea of perspective distance in a picture, while Schrenk, employing two very simple pictures, concluded that perspective is first understood at the average of 13.6 years. He inferred that at the age of 10 but 50 per cent of boys have developed feeling for perspective, this becoming manifest in girls only at 13. The *drawing* of a design in perspective must, therefore, be impossible at these earlier ages. One can even understand how an older child, *seeing* this drawing in perspective, might be greatly puzzled in reproducing it (an utter impossibility if it has not had special training in the technique of tridimentional drawing).†

The irregular figure of Ziehen is, in our opinion, a far better model than those of Binet, to employ as a visual memory test of a difficult design. It is neither too simple nor yet too difficult, and affords little occasion for "associative anchorings" (quite the contrary being the case with Binet's designs). Most ten-year-olds will be able to reproduce the *idea,* or *plan,* of this. It is passed if the right salient is larger—is broader and extends higher—that the left. As to the base line, if this is reproduced tilted, as in the model, the performance must be considered an exceptionally good one. In the try out mentioned above I found the technical execution itself very poor indeed, up to the age of thirteen. One may stimulate the attention when placing this drawing before the child by saying, "Now, look very carefully at this, and get the *idea* of it."

That a special *memory type* in a child might influence these tests negatively (and it makes us again bear in mind *memory types,*[5] is seen in the following instance: Meumann[16] once observed a boy of thirteen trying to draw an outline map of Greece. "Although the boy had made an accurate study of the map, his drawing did not show the characteristic outline, but only a shapeless form, which bore no resemblance to the map of Greece. I surmised at once that he belonged to the motor type and had him trace the coast line with his finger, at first in sections, and then as a whole. He was then able to make the drawing accurately and without any difficulty." Meumann mentions that Binet also determined that certain persons must trace a drawing with the finger if they are to remember it.

And now let us note the essential facts to be deduced *en resumé* from our consideration of the foregoing test. We find there is much more in question here than visual memory; in fact, visual memory is the least important element contained. The drawing process entails seeing (eyes and visual centers), the imprinting and retention of distinct (visual) images, their association (and cortical

*If the child is satisfied with the drawing just made, one goes on with (2); but if the child is not satisfied or wishes to try again, it is permitted to make a second drawing and to choose one of the two. Under (2) but one drawing is made and one minute is allowed.

†Memory for form, by the way, varies greatly in different individuals. Cf. (No. 11), p. 229.

‡Terman says "correctly means that the *essential plan* of the design has been grasped and reproduced. Half-correctly means that some essential part of the design has been omitted or misplaced, or that parts have been added.

*Cited by Meumann.[15]

†(No. 15, Vol. III, p. 750.)

interassociation) in the act of enscoping and comprehending the thing to be drawn (analyzing and construing vision), finally association and co-ordinations with the motor aria, and from here with the eyes on the one hand and the muscles of the fingers and hand on the other. Or one might more briefly segment the process into three links, *seeing*, *understanding* and *dexterity*.

An individual may have an unschooled, undeveloped way of seeing—this is remediable; or there may be an innate defect of form-memory, *i.e.*, the visual images imprinted are not distinct, are but vague or fragmentary (or the visual association tracts poorly developed?). In individuals of strongly acoustic or acoustic-motor ideational type, such deficiency or defect in visual centers may be particularly noted, at times even severe enough to influence their "visual understanding" in general. In spite of these innate abnormalities (defects) intelligence may be intact. The defect may also, as we have seen, be camouflaged through reflection, etc. The passing of part (1) of the drawing test is therefore in no wise *intelligence-diagnostic*, its failure in no wise *defect-diagnostic*. But failure in the test may also be due to manual disability, to incapacity in graphic expression, visual memory and understanding being normal. This would be shown if the test-person could recognize pictures of the thing, and especially could verbally describe it. Such manual disability is more often found in the less endowed than the better endowed, but *may* exist in even the very best endowed. It is, therefore, not even remotely *defect-diagnostic*, nor is especial adroitness *intelligence-diagnostic*.

Understanding, "analytical and construing seeing," is not so easily disposed of. It entails intercortical associations (cf, the remarks on comprehension in our *foreword*). It will be discussed more carefully under comprehension of forms, objects, etc., in the rubric on Comprehension. Here we may say that empirically it has been shown that the square is grasped earlier than the triangle and diamond;* simple, symmetric geometric forms earlier than assymmetric, these earlier than forms *in perspective*. In the graphic reproduction of the designs—and we consider now merely the reproduction of the *idea*, the general *build*, of the design, omitting the element of technical execution, the child must gage its own drawing, in the process of construction through comparison (repeated comparison) with the original, must pass upon (and carry in mind—here the element of optic memory enters strongly) the length, proportion and tilt of the lines, angles, etc., correct errors, suppress irrelevancies; in short, exercise critique and maintain a purposed direction. Such power of purpose is largely a matter of tenacity of attention. Here autocriticism is added, or rather superimposed—and the power of critique correlates high with intelligence. In the test the actual drawing may do but little justice to the child's *intention*. As Meumann pointed out, the very incongruity between the intention and the drawing in progress may disconcert, may mar the performance. Hence, its verbal opinion is of greater importance. Indeed, in these drawing tests we must conclude that the child's verbal crticism of its performance is of greatest importance—is, in fact, the real element of importance. When well done, this is decidedly *intelligence-diagnostic*, and when badly done—vision, etc., not being defective—is significant of poor endowment (at times, of defect).*

As to standardization, nothing has been done regarding this part (3) of the drawing test, aside from which, as we have seen, the test (the test as hitherto given) has very questionable value. From the data on hand on part (2), the age norms may be approximately placed as follows:

Drawing the square.....at 4-5
Drawing the triangle.....at 6-7
Drawing the diamond .....at 6-7-8†
Drawing Binet's designs.....at 10-11-
Drawing Ziehen's design.....at -10-‡

Tests (h)—the learning test: Several of our tests have involved momentary impressibility, *i.e.* infixing (on hearing the memorial matter just once) for immediate repetition. In such tests, verbatim recall is only possible if the material is within the memory span, and when accomplished, means no more than that the impression (really the perceptional after-image) has lasted long enough for just immediate reproduction. It does not mean that the matter has been *memorized*, has been impressed for extended or permanent retention. Very little, if anything,¶ on one presentation, can be impressed for exact recall that is lasting. To that purpose it must be *re*-impressed, must be *learned*.

When we come to material that is longer than the memory span, that cannot be exactly reproduced on one presentation, we find that if repeated often enough—if *learned*—it is soon reproducible for one or more correct renderings. But even here its reproduction does not mean that it has been really *memorized*, that it has been impressed for deferred or permanent recall. Thus it has been shown that senseless material learned in this way is never reproducible on the following day, and that even sensible material at one sitting will rarely stick (No. 16, p. 269). *Learning* and *relearning*, then, are of fundamental importance, psychologically and pedagogically, for real retention, and the acquisition of knowledge depends upon these factors.

The *infixing* and *learning* processes should therefore, be distinguished and separately examined. A special admonition to this effect comes from the domain of psychopathy, in which it was found that certain individuals, in spite of an inability to reproduce much (within the memory-span) on one pres-

*The circle earlier than the square.

*In young children, however, criticism will be found of a very simple nature and given with very few words. The paucity of words may make such criticism difficult to evaluate.

†The children on whom this test was tried (see above) were a high-typed group, so that for average children this test may also fall into the 10-11th year.

‡Remembering Bobertag's statistics. But 61 per cent. of his 7-year-olds passed.

¶Such lasting impression may occur, however, when the matter is associated with very great or intense tonal feeling. Ordinarily, however, as learning material is constituted in the school, in the home, and in everyday life, repetition is necessary for real infixing. The innumerable *psychoreflexes* which are established in childhood and which in such large measure determine our ideation and behavior, likewise originate through repetitions, though some are also forged on single incidence through strong tonal feeling (affects). See No. 1.

entation, could do so after several presentations: their infixing ability was impaired, yet they could make good through their capacity *to learn* (Cf. No. 3, part 3).* But pedagogics itself points the way in its differentiation of the slow and the rapid learner. The former can retain little on one presentation. He must go over and over a thing before it soaks in and holds. The difference between both types is striking where mechanical memory is involved, less marked, however, for retention of significant material (Meumann). The slow learner is so because his infixing is poor, his memory span narrow, his accommodation of attention labored. But after the learning task is once accomplished, his *retention* is good, is possibly superior to that of the facile learner. Each type has advantages, yet the slow learner, the child which must repeat, is not inferior in intelligence to the other (though intelligence tests which do not take these diagnostic points into consideration might make it appear so). On the contrary, he may be superior. Thus Pyle writes, "If a slow learner has the habit of going over a lesson or task several times, and a fast learner the habit of giving a lesson but one hasty reading, other things being equal, the slow learner will have the better scholarship (Cf. No. 9, p. 583), while Meumann, Radossawljewitsch, and Höffding have intimated that the rapid learner also forgets the more rapidly.

All tests of immediate memory, or let us say, rather, all tests of one presentation, must be evaluated with an eye on this learning test. When the former fall out poorly, possible this latter will offer an explanation and extenuations. Here in connection with the relearning and saving computation we may diagnose the poor infixor, the slow learner, yet after all, the good retainer. Here again we may spot the rapid learner, who is likewise a good retainer—the most propitious type of learner. Finally, the out and out poor scholar, poor in infixing, in learning and in retention, may here come into evidence.

As to the learning capacity itself, without being able to standardize norms (for significant material), we know that it increases with the years (well into the forties—and need not lose its edge, even in the fifties).[22] On the other hand, retention, contrary to what we would expect, *decreases* with the years, is less in the adult than in the child, less in the older child than in the younger (at least, up to 6 or 7). Or to put it reversely, the child, though learning less ably than the adult, retains better what it once has learned, and the younger the child, counting from the sixth or seven year on,† the firmer the retention.

The test procedure itself is as follows: One presents sensible material*—a sentence half again as long as the memory span—to the test person, and after two presentations has the sentence repeated, then presents it again, and has it repeated, etc., etc., until it can be recalled without error. One then makes note of the number of repetitions necessary for one correct rendering. On the following day (24 hours later) one repeats the experiment and determines how many fewer presentations (reproductions on part of the test person) are necessary for the correct recall. The difference between the number of repetitions of the first and second experiments is the *saving* in repetitions—*i.e.* the index of the retention.

Ebbinghaus (l. c.) elucidates as follows: "If a person takes 50 repetitions to learn a 12-syllable line for one correct repetition, and after eight days takes 25 repetitions, the saving is 25 repetitions. This 25 is the absolute saving; the relative saving is ½ or 50 per cent. If a line is learned with 50 repetitions, and 30 days after is learned with 40 repetitions, then the absolute saving is 10, and the relative 1/5, or 20 per cent. These values are at the same time measurements of *forgetting*. The measures of forgetting are the complements of the figures of retention. In the first instance, the retention was 50 per cent., so also the forgetting; in the second, the retention was 20 per cent, the forgetting 80 per cent."

But how does this second relearning compare with the original learning? It has been claimed (Meumann) that the child who learns slowly also relearns with difficulty. Some doubt is thrown on this fact—at least upon its universal application—by Müller and Schumann (Cf.[22] p. 686), who had three test persons learn lines of twelve senseless syllables. This was accomplished with 11, 14.8 and 19 repetitions respectively. Twenty-four hours after the same were relearned with 7, 8.2 and 8.7 repetitions. Here it was found that the *saving* was 4 (37 per cent.), 6.6 (or 45 per cent.), and 10.3 (or 54 per cent.). The interesting point here lies in the *relearning* feat, for in this the rapid learner hadn't by any means much advantage over the slow learner. And Ebbinghaus intimates that his own results, as also those of Ogden, seem to corroborate these facts.

This lifts the *relearning* phenomenon into significance of its own*, and it might be well to consider this rate itself in comparison with the rate of the initial learning, besides using it to determine the *saving* and percentage of retention.

Here it might also be pointed out that the experiments of Ebbinghaus, Meumann, etc., show that the first repetition or relearning, after the initial acquisition (*i. e.*, the "freshing up" on the following day),

*Interesting in this connection is the report of Gregor (l.c. No. 13) that in using four pairs of one-syllable words with one presentation, on a group of mental patients, he got 24 per cent. of correct associates, but on employing two presentations he obtained 62.5 per cent. As to repetitions, however, Hawkins, on normals, found two hearings less effective than one or three. Smedley's test of 38 ten-year-old pupils with auditory digits gave for the first hearing 47 per cent., for the second 55 per cent., and for the third 59 per cent. correct reproductions. But in some of Smith's tests, 12 presentations did not double the efficiency attained in one presentation. (Cf. No. 9, p. 558).

†Earlier than the sixth year retention appears to be very unstable.

*An immense amount of experimental work has been done with this learning test, really the cornerstone in experimental memory psychology, and from the results many of the fundamental laws in pedagogics have been derived. The experiments have been mostly with senseless, far less so with significant material. For the learning test, as we wish to apply it, significant material should be used, as that is the kind the child is concerned with as a learner in the school, as well as out in daily life. (Cf. No. 15, Vol. I, p. 452, who states that he does not see how the conclusions derived from senseless material are to be applied to the child whose learning is of significant and never of senseless material.) The learning test comprised of a set of symbols and key numbers, a long series of symbols then to be rapidly numbered (frequently employed among army tests) may be criticized from the same viewpoint. It is difficult to see just what it has to do with intelligence.

is the all-important factor for real retention; subsequent repetitions serve only to intensify its effect. (No. 16, p. 334.)

Our paper has grown too long to include a study of the Reliability of Memory, (i). These tests are separated from the remaining memory tests, it will be seen (cf. test-sheet), they being qualitative tests and not intelligence indices in the stricter sense. Under (i) I. The story (same as test (c)) is recalled at the end of the test session, and on the following day. The same procedure is undertaken, II, with the Christmas-picture (likewise used under *Comprehension* (g)). Under III a cardboard with two small pictures and four small objects pasted upon it is exposed, then covered, etc. (see Whipple on Fidelity of Report). IV. Certain misleading questions are applied to tests I, II, III, in order to bring out the test-persons' suggestibility.

Among the nine tests under the rubric of Memory, only one is of prime importance as an *intelligence endowment* test (i.e. test of especial intelligence) and that is (d) II. It may be applied at all ages; on the other hand, it cannot be used as an index of a special age norm. Nor does test (d) I, serve very accurately for this latter purpose. Among this group of tests, test (a) does this best. If one knows how to make proper allowances and deductions in using test (g), the drawings accomplished may aid in this matter. The autocriticism in this test will also serve as an index of *intelligence endowment.*

Test (c) is probably the most important test as yet at hand in "borderline" diagnoses.

For the substantiation of normality (or abnormality), of infixing, retention and recall, and of immediate and deferred recall, tests (a), (b), (d) I, and (f) will serve.

When tests have fallen out poorly, *and in all cases of psychopathy,* the attention span must be especially studied, and the *learning,* relearning and saving estimated. Thus, for abnormal (psychopathic) cases, test (h) is the most important test. For pedagogical diagnosis this test may also be used to decided advantage.

As to the remaining tests in our series—which will be discussed in detail in subsequent publications—some will be found evident enough, as given on our test-sheet, to apply without further explanation; others will be familiar from the Binet series. Under *Comprehension,* test (a) is such. The test immediately below this is Meumann's. Test (b) under Comprehension is Bobertag's and will be found explained in our earlier study, No. 5. This test differs materially from Binet's and the change is of decided importance. Test (c) is Meumann's. This and the remaining Comprehension tests up to the age of fifteen are also described in No. 5, though not as thoroughly as with our present knowledge we should wish this to have been done. The picture used under (g) is a most excellent picture for intelligence examination, as are also the three employed by Bobertag—all of which are contained in our set (the five obtainable from A. T. Beals, 228 West Twenty-third Street, New York).

Under *Combination* the age norm for test (e) is given by Bobertag, likewise the special method "with the aid of questions." Test (f) is Ziehen's. Test (h) is De Sanctis' (*l. c.* No. 5). Test (i) is Meumann's (see *Zeit. f. Pād. Psych.* 13 Jahr. H. 3, p. 145, etc.). In this study of his will also be found the excellent test of composing a story out of a set of stimulus words.

The Genus Epidemicus of Influenza Pandemics.—No one doubts that in the recurrence of vast waves of influenza, some third cause is concerned beyond a germ and the human organism. This is usually taken to be some climatic or meteorological condition. Magelssen, a Scandinavian has studied the weather conditions in Christiania for over eighty years back or beginning with the epidemic of 1847 and has compared the weather of influenza years with weather in general. Before the pandemic of 1918-19 and all other epidemics an intensely cold winter was followed suddenly by a hot dry summer. Now there can be no line of demarkation drawn between common colds, winter epidemic catarrh, and the pandemics, so that climatic conditions alone must decide on the incidence of these affections. Winter alone is sufficient to render colds prevalent and when a very severe winter passes without transition to a hot summer the resistance of the individual must be greatly affected. There is the same lack of adjustment as is seen when an individual goes suddenly from a cold to a hot climate. The author shows by graphics that this vitiation of the resistance tends to persist for about three years at least. The young and robust are attacked wholesale because they are the very ones who draw most on the reserve by a life of physical exertion displayed in games, dancing, overwork, etc.—*Office International d'Hygiène Publique.*

Medicolegal Notes.

Practice of Neuropathy Is Practising Medicine Under Pennsylvania Statute.—In a proceeding for practicing medicine and surgery without a certificate of licensure from the Pennsylvania Bureau of Medical Education and Licensure, the principal questions contested were: (a) Is the practice of neuropathy the practice of medicine? (b) Is it the practice of a branch of medicine or a separate science? and second, Is the Pennsylvania act of 1911, as amended, requiring a certificate to practice medicine and surgery constitutional? The treatment given by the defendant to his patients consisted of manipulation around or about affected parts of the body, no drugs or medicine being used. The Pennsylvania Supreme Court said that the determination of the questions raised must depend on the proper understanding to be derived from the words of the statute involved. Of controlling importance was the word "medicine," a word susceptible of distinct meanings; one indicating nothing more than a remedial agent that has the property of curing or mitigating diseases, or is used for that purpose, while the other indicates an art of healing or science which has for its province the treatment of diseases generally. The latter has much the wider and more comprehensive significance, of course, and while, as so used, it may be in a sense technical, yet unquestionably the wider is the popular sense in which it is employed and understood. Furthermore, whatever is technical in it has so far been popularized by common usage and understanding that no one, however unlearned, can fail to observe the true distinction between medicine as a drug and medicine as a science or profession. It is in the latter sense that the word is employed in the Pennsylvania statute. Manifestly, to construe it otherwise would be to defeat the object and purpose of the legislation. The legislative purpose with respect to it is expressed in the preamble to the act, as follows: "Whereas, the safety of the citizens of this commonwealth is endangered by incompetent physicians and surgeons, and a due regard for public health and the preservation of human life demands that none but competent and properly qualified physicians and surgeons shall be permitted to practice their profession."

The one danger provided against was, not the promiscuous sale of drugs or other remedial agents, but the unrestricted and unregulated practice of medicine or the art of healing; medicine here being used to denote an art or science having for its object the cure of diseases and the preservation of health, whether with the aid of drugs or any other remedial agencies whatever. The manifest and only purpose of the statute was to confine the right to invite public confidence in the skill and efficiency of those who would hold themselves out to the public as medical doctors to those only who have had an examination by an impartial board of examiners created by the statute and acting for the state, and have been accredited by that board as having met the requirements of the law and received its license. The policy of the law in enforcing such regulation under its police power is not questioned; no more is the wisdom of the enactment. Giving the act this interpretation, the defendant was held to have brought himself within its terms; he engaged in the practice of medicine, that is, he held himself out to the public as one instructed and skilled in the healing art. The distinction that was sought to be made between neuropathy and medicine could avail the defendant nothing, in view of the legislative meaning of the latter word, which, when used in the expression "practice of medicine," covers and embraces everything that by common understanding is included in the term healing art. The defendant held himself out to the public and invited its confidence and patronage as a "practitioner of neuropathy." The use of this term necessarily implied that he was skilled in the science of pathology, a science unquestionably which has for its province the treatment of diseases, their nature, causes, progress, manifestations, and results. This to the lay mind, no less than the professional, would import that neuropathy was a branch of medicine. What more could be said of allopathy, homeopathy, or any other science of healing with such termination as its adopted designation? The terminology, in neither instance, indicates to the general public what remedial agents are employed by those practicing the particular science, nothing beyond the fact that, whatever else it might mean, it does certainly mean that the art or science practised in this instance has for its object the cure of diseases and the preservation of health. To assume that it is not such science is to classify the practice of it with empiricism. It was not pretended that the defendant violated the statute by healing diseases by the use of medicine, that is, drugs; but it was specifically charged against him that without a license he had held himself forth as a practitioner in medicine and surgery. On the evidence adduced the judgment was affirmed. The statute was held constituional.—Commonwealth v. Seibert (Pa.) 105 Atl. 507.

Representations as to Health and Consultations in Insurance Application.—In an action on a life insurance policy, applied for and payable in Colorado, where the defense was misrepresentation in the application as to consultations with physicians and the existence of disease, a number of physicians testified as to consultations with the insured and the results thereof. While some of these consultations were for minor and temporary ills, others tended to show, and all of them might be regarded as showing, that the insured was suffering with chronic nephritis and that he knew it. It was held that a secret, insidious disease like Bright's disease might be wholly unknown to the applicant, and, if so, even if he did have it, his answer that he did not would not entitle the defendant to rescind, unless the applicant had warranted that he did not. But the applicant was bound to know whether he had consulted any physician and would be able to give the names of the physicians consulted, or, if he could not recall their names, to state that fact, and then the company would be in a position to determine for itself whether or not it would enter into the contract. The applicant ought not to be permitted to withhold such information and yet nevertheless the beneficiary be allowed to recover on the ground that the fact of such consultations and the ailments for which they were had were immaterial and had no influence on the question of whether the contract should be entered into, or did not result in causing the insured's death, since that would be depriving the company of the right to decide for itself whether it would take the risk of the applicant's insurance. That would be permitting the applicant to decide for the company the important question of whether it would insure the applicant's life. Mere failure to recall and state that a doctor was spoken to for some simple trifling matter, having no significance either to doctor or patient, might not in all cases justify a rescission of the contract. But where there has been a continuous and repeated consultation of physicians extending over a period of time, with circumstances likely to cause apprehension to the mind of a reasonably prudent person that perhaps there might be some reason for suspecting unfavorable conditions, and possible grounds for not accepting the applicant as a risk, then a failure to make full, complete, and true answers ought to afford ground for rescission if not otherwise waived and such failure is acted upon promptly. For these reasons judgment for the plaintiff was reversed.—Lewis v. New York Life Ins. Co. (Mo.) 209 S. W. 625.

Statements to Physicians as Hearsay.—Declarations made by one injured to his attending physician are admissible when they relate to the part of his body injured, his suffering, symptoms, and the like, but not if they relate to the cause of the injury. Under this rule, where an employee died from an infected wound in his arm, it was held that evidence of his statements to his physician and his wife that he suffered the wound while in the service of his employer was incompetent in a proceeding under the Illinois Workmen's Compensation Act.—Spiegel's H. F. Co. v. Industrial Commission (Ill.) 123 N. E. 606.

Dying Declarations.—The Alabama Supreme Court holds that in a homicide case, the statement by the deceased after he was shot that "C. killed me, but he has not scared me," and "I am not afraid to die," was sufficient preliminary proof of the deceased's consciousness of his impending death to permit the admission, as a dying declaration, of a statement by him concerning the difficulty which led to his death.—Carden v. State (Ala.), 82 So. 423.

THE PATHOGENESIS OF CONGENITAL CYANOSIS.

THE pathogenesis of congenital cardiac defects has been variously explained. Some observers have regarded an interventricular communication a paramount condition of congenital cyanosis and place cardiac malformations among the anomalies of reversion. But an interventricular communication rarely exists alone and when it is associated with a stenosis of the pulmonary artery, which is a common occurrence, this explanation cannot be invoked. Then the theory of fetal endocarditis was put forward, having for a basis the frequency of stenosis of the pulmonary artery, which, for some, should be the starting point of various other lesions. This theory might explain the interventricular communication since the septum becomes occluded the last. The deviation of the origin of the aorta is the consequence of the forcing back to the left of the interventricular septum which projects into the left ventricular cavity.

The theory of embryogenic disturbance originated in Germany, where it was maintained that the stenosis of the pulmonary artery was due to an abnormal division of the bulb. When this division does not take place a single arterial trunk results or else the division is unequal, resulting in stenosis of the pulmonary artery. It may happen that the arterial septum, by approaching the anterior wall, acts in such a way that the aorta is deviated to the right and backwards, while the stenosed pulmonary artery is to the left. Poirier maintains that the septum dividing the arterial trunk develops from above downwards and that its formation is independent of that of the interventricular septum. It unites with interventricular septum forming the upper portion of the septum known as the "membranous portion," thus resulting in a complete separation of the two ventricles. An interventricular communication might be explained by a displacement of the septum to the right, the lower part therefore being unable to unite with the upper part of the septum.

The objections to fetal endocarditis are: (1) Cases have been observed without any macroscopical or histological evidence of endocarditis. (2) The inflammatory theory cannot explain the absence of any division of the arterial bulb and transposition of the arteries. (3) It has been pointed out by Moussous that the stenosis of the pulmonary artery should exist during the early weeks of intrauterine life in order to provoke an arrest in the development of the ventricular septum; yet more, the dividing off of the arterial bulb takes place only a few days before that of the ventricles, so that an endocarditis in the early days of intrauterine life should involve both the aorta and pulmonary artery. To involve merely the latter, it would have to appear at a precise date, at the end of the sixth week, for example, and cause a stenosis in the course of a few days. Now, stenoses in general, even of a duct of small caliber, are not formed in a few hours or days. (4) It seems too one-sided to regard all cardiac defects as depending upon a stenosis of the pulmonary artery. In point of fact an interventricular communication may exist alone, being the pathological characteristic of Roger's disease; and the same is true of a patent Botal foramen. Yet more, a stenosis of the pulmonary artery is not a permanent condition in cases of congenital cardiac defects.

The theory of embryogenic disturbance cannot be sustained. To this theory the objection has been raised that pathological examinations reveal the inflammatory nature of the cardiac lesions; for some it is secondary, while Moussous maintains that congenital cardiac defects predispose to eudocarditis, this process attacking the most vulnerable points, namely, those which are the seat of a defective embryogenic development. It has been maintained by competent pathologists that the changes arising in the endocardium and pericardium are more important in older children and adults and are rare or little evident in very young children, infants, and the still born. The persistence of the pulmonary trunk after stenosis of its initial portion has taken place has been denied, being a notion hardly comprehensible in the case of arrested development. In opposition to this objection it is pointed out that the pulmonary artery arises from the fifth aortic arch, the aorta from the fourth, and that the formation of the trunks is independent of that of the bulb.

It has also been maintained that the lesions are more frequent on the right, but other observers believe that this is only apparent because the lesions on the right are the only ones compatible with life; those on the left would cause death during the early phase of embryonal life. It would therefore seem that in the present state of our knowledge a congenital cardiac defect resulting from some embryogenic disturbance is the most likely pathogenesis of congenital cyanosis.

ENCEPHALITIS LETHARGICA.

A RECENT number of *Il Policlinico* (xxvii, 4, 1920) is devoted almost wholly to this interesting disease, or syndrome. The first paper is by Sabatini and is devoted to clinical manifestations. There is a triad of symptoms, he says, comprising somnolence, ocu-

lar pareses, and the constitutional reaction, and he suggests the name epidemic encephalitis as an analogue to epidemic poliomyelitis. There are a number of special clinical types which do not interfere with the triad of symptoms. They depend for their individuality on the order of evolution of the symptoms and of superadded phenomena. Thus we see patients with somnambulism and with disorientation. In some cases herpes febrilis accompanies the temperature rise. The author isolates these types: lethargic in which this symptom dominates the picture; hyperkinetic in which the subject is restless, complains of neuralgic pains, shows heightened reflexes and in general many phenomena of muscular excitability; a paralytic form which is the antithesis of the preceding, and a mental form in which affects are common with motor automatisms. Giuseppe discusses the bacteriology in three cases, but despite the thoroughness of his study and the numerous partial finds he does not make out any case for a causal bacterium. Oggero reports 4 cases in full. These appeared to be of the irritative type suggesting meningeal involvement and there are a few similarities in incidence to epidemic cerebrospinal meningitis. The mortality in the local epidemic was also high 35 per cent, which fatality suggests the other malady. Leopoldo writes of the affection as it occurred in Trent, but reports only a single case. Fornara also reports one case of the irritative type—violent agitation, delirium, etc., with neither fever nor ocular troubles at the outset. The muscles were hypertonic, with myoclonic movements. It is suggested that the infectious disease known seventy-five years ago as electric chorea was of this nature, somnolence having been a symptom of that malady. Several other papers are found in this number and in one by Modena the name "polioencephalitis infectiva" is proposed for the affection.

Writing in *La Riforma Medica*, xxxvi, 4, 1920, Montefusco gives a concise summary of our knowledge of the affection since the influenza pandemic of 1889-90. There first appeared during the decline of this pandemic a mysterious malady in the province of Mantua which received the name of nona. A few cases came to light during the nineties, but not until 1900 did Bozzolo term it acute polioencephalitis of influenza. During the recent appearance of the malady cases occurred in Lombardy, Piedmont, Naples, and elsewhere in the Italian provinces. Most striking is the appearance of the disease almost simultaneously in most of the countries of the globe, including Africa, Australia, South America, etc., as well as in Europe and North America. This global incidence suggests that the disease occurred in the wake of influenza although it is now said to have appeared in force in 1917, not alone in Austria but in Australia, thus long anticipating the pandemic as we know it, though not necessarily negativing a relationship between the two. It has certain features in common with three other infectious maladies, viz., epidemic meningitis, acute anterior poliomyelitis, and cerebral influenza. Like the former it shows weak diffusibility and—at times at least—high mortality; but the fact that the cerebrospinal fluid is normal in lethargic encephalitis is final even if there were not plenty of other convincing proofs, such as the known cause of meningitis. Its minute anatomy suggests that of the cerebral form of infantile paralysis, while the chief suggestion in connection with influenza is the incidence in the wake of the pandemic. At present the evidence that the disease is autonomous seems to be increasing, and until we learn more of it, it can only be said that it belongs to a common group with the three other maladies and that it may eventually prove to be more a syndrome than a disease.

SUBSIDIZING THE DOCTORS.

CERTAINLY nobody is better versed in the difference between trades and professions than is the man engaged in medical research. He spends his life in acquiring information from grudging Nature, instead of in acquiring dollars from grudging competitors. He has no wares to sell. Even his language is all his own. His results may be merely negative, disproving this or that. Or he may get no results at all,—that highest of crimes in the world of trade. More rarely, years of "no results" may end in a brilliant discovery which relieves much suffering—witness Pasteur's work on rabies. Now there is little doubt that in the end society wants this sort of work done for it. Society knows very well that it is to be congratulated on the discovery of diphtheria antitoxin and of vaccination against smallpox—even more than on the negations of the Christian Scientists and the antivaccinationists. The more intelligent can be got to admit that they owe a great deal to scientists who spend their lives in research on disease. But so far as society in general is concerned, the debt goes unpaid.

It is all very well to say that we can never repay the man who has saved so many thousands of children from smallpox, or so many thousands of soldiers from typhoid fever. But we forget there are no short cuts to such splendid results. We forget that money, as well as time and industry, is required; that at the present moment work is being done which is bound to lead to advances just as remarkable; that the people's responsibility is to pay such debts in advance. Scientists are much more interested in meat and potatoes during life than they are in statues and memorial hospitals after they have gone to their often obscure death. But for the enlightened charity of a few rich people, only that *rara avis*, the congenitally or matrimonially wealthy investigator could indulge in the expensive vocation of scientific research.

Consider also the common garden variety of doctor, the man who engages in private practice. Here is an individual in whom the much-rebuked public takes a far more active interest. He too is not a tradesman with wares to sell. But he is a man whose advice and treatment they must often

seek, and whose bills they should, at least, pay. The practitioner is also a financial hanger-on, but only a temporary one, that is, until he gets to the bill-sending stage. And that may be a long time. In spite of the fact that there is probably no harder working group of men, professional or otherwise, it seems to have been decreed that they should be members of the "leisure class" in order to pursue the study of medicine to the best advantage. (A tendency to celibacy is also advisable, though often lacking.) The financial balance of the recent medical graduate favors output rather than intake to so great an extent that only an adequate family exchequer or a remarkable ability to make money during off hours can tide him over the necessary years of training. And even then, though chances to do free work abound, remunerative work is painfully scarce, and usually of little scientific value.

The points which we have been considering would seem to add several important reasons to the many already clear, for the establishment of a National Department of Health with a representative in the Cabinet. One of the functions of the Department should be the correlation and centralization of the efforts of medical investigators. Eventually it should be possible for the Department to finance such research through appropriations. This of course is in the nature of prophecy. Research financed by private individuals has certainly proved its value. It has had the added virtue of being free from politics. To date "State Medicine" has not distinguished itself; and attempts at it have usually left the medical men "out of luck." The principle, however, should be kept in mind. Those who are qualified to engage in medical investigation should be regarded as public servants. They must continue to be the objects of private charity until the State shows itself equally qualified to support and encourage work of this kind. Meanwhile Government clinics should be opened in increasing numbers, offering pay positions to the younger men, together with opportunity to carry on special work on various diseases. In other words there are many ways in which the Government could assist and encourage medical men, through such an agency as the National Department of Health. There are many ways in which the Department could facilitate the work of representative medical organizations. If the growing tendency to socialization of medicine could follow these lines rather than those indicated by lay politicians, the outlook for the profession would be bright both financially and scientifically.

Mild Botulism with Multiple Eye Symptoms.

In the cases reported of late we note much fatality in cases with ocular symptoms as ptosis and internal strabismus, but Caussade at a recent session of the Société de Médecins des Hôpitaux de Paris reported in behalf of a Toulouse practitioner four cases in soldiers who seemed to have recovered but who had suffered from a number of eye symptoms which were very slow in receding. (*La Presse Médicale*, January 21, 1920, xxviii, 6.) The vehicle for the poison was smoked trout. The initial gastrointestinal and nervous symptoms were typical and the eye symptoms were in part those which have usually been seen, including ptosis, mydriasis, diplopia, accommodation paralysis, and amblyopia, but with the addition of intense congestion of the optic nerve and retina and contraction of the visual field. These two symptoms are rarely found in literature but are doubtless responsible for the amblyopia which is so often present. Authors who mention the resemblance between botulism and wood alcohol poisoning state that ptosis is the only approach to loss of vision, but the author's cases show that in both the nerve and retina suffer. In addition botulism resembles other kinds of food poisoning, including that from poisonous mushrooms, and also various affections in which ophthalmoplegia occurs, such as meningitis and syphilis.

Causes of Sterility.

The causes of sterility necessarily vary much with the material and stand out most pointedly in those women who normally rear large families and use no preventives of conception. In *Il Policlinico*, for December 7, 1919, xxvi, 49, Brun of Trieste gives an analysis of 300 cases seen in Trieste during the past ten years. Of this number 230 were examples of primary sterility and in 107 of these anatomical defects were present in the genitals, while in 102 sterility was attributed to inflammatory affections. In 13 women no causal factors could be found, while 8 others owed their sterility apparently to fibroids. Of defects of the genital apparatus the most common types were infantile uterus, pathological and extreme anteflexion and ovarian insufficiency with obesity. Retrodeviation was represented in but 10 cases. The most common inflammatory affections were chronic salpingitis and perimetritis, other types being poorly represented. Of the 70 cases of secondary sterility the chief cause is the same—chronic salpingitis and chronic perimetritis—with 44 cases, the other causes being scattered.

News of the Week.

Women's Medical Society of New York State.—The fourteenth annual meeting of the Women's Medical Society of New York State was held at the Hotel McAlpin, New York City, March 22, under the presidency of Dr. Elizabeth Burr Thelberg of Poughkeepsie. The morning session was largely devoted to official reports and other executive matters. The following scientific papers were presented: "Recent State Laboratory Work in Vaccines and Serums," by Dr. Mary B. Kirkbride, Bacteriologist of the State Department of Research; "Dr. Mary Jacobi, a Medical Pioneer," by Dr. Annie S. Daniel of New York City (by invitation); "Report of the American Women's Hospitals," by Dr. Esther P. Lovejoy of New York City; "Industrial Fatigue," by Dr. Winifred Cullis of London, England; "Relation of Gynecology to the Glands of Internal Secretion," by Dr. Lillian K. P. Farrar of New York City; Discussion of

Dr. Farrar's paper by Dr. Emily Lewi of New York City (by invitation); "Diabetes," by Dr. Helen Baldwin of New York City; and "Technique of Diagnosis of Visceroptosis," by Dr. Eliza M. Mosher of Brooklyn, N. Y.

At the banquet in the evening Dr. Cullis told of the work of English women in the war and of the early attempts of women in England to study medicine; Mrs. Henry Villard spoke on the influence of medical women; Dr. Esther P. Lovejoy discussed the International Medical Women's Association which was organized last fall; and Dr. Rosalie Slaughter Morton told of her recent trip to Serbia. Dr. S. Josephine Baker was toastmistress. Among other speakers were Dr. Martha Walstein, Dr. Grace N. Kimball, Dr. Elizabeth Burr Thelberg and Dr. Lois L. G. Gannett.

The following officers were elected for the ensuing year: . *President*, Dr. Lois L. Eastman Gannett, Adams; *First Vice-President*, Dr. Florence I. Staunton, Utica; *Second Vice-President*, Dr. Maihilda K. Wallin, New York City; *Third Vice-President*, Dr. Louise M. Hurrell, Rochester; *Secretary*, Dr. Harriet M. Doane, Fulton; *Treasurer*, Dr. Elizabeth L. Shrimpton, Syracuse.

A Demand for Amendment of Certain Objectionable Laws.—The following is the substance of an open letter sent to the House of Delegates by Dr. Davin of this city, on behalf of a number of the members of the Medical Society of the State of New York. In it attention is called to (1) The Medical Fee Bill of the Workman's Compensation Law, (2) Compulsory Health Insurance, and (3) the State Narcotic Drug Laws. It is stated that at an investigation in this city of the Workmen's Compensation Law, a medical witness testified to receiving fifty cents for each service rendered. At the same time the statement was placed upon the record that, under this law, the injured workman was receiving the poorest and cheapest form of medical service, due to the fact that physicians and surgeons of standing, according to their own declarations, were refusing to treat compensation cases. Nothing, however, has been done by the Society to secure a change in the medical provisions of this bill. Although the State Society is now on record as unanimously opposed to Compulsory Health Insurance, in order to make this stand effective it should present this attitude of the medical profession on this question to the people and Legislature in a manner which would compel attention. A repeal of the present Narcotic Drug Law should be demanded, as under its administration it has proved to be inhumane, oppressive, and unscientific.

Government Takes Over Speedway Hospital.—The long controversy over the Speedway Hospital, Chicago, said to be the largest of its kind in the world, ended when the hospital finally became the property of the Government. The total appropriation for the project by Congress is $3.500,000. The contract taking the hospital over from Edward Hines, who says it represents an expenditure of at least $5,000,000, was signed by Secretary of the Treasury Houston, and the first payment is to be $1,400,000. The name of the institution is to be changed to Broadview Hospital. The hospital is to be used for rehabilitation work. The building is 2040 feet long, five stories high, and is fireproof throughout. The main building will have accommodations for 2500 patients, and four more buildings are to be constructed as a part of the plan.

Convalescent Camps for Soldiers.—Special arrangements have been announced by the New York Community Service for the establishment of summer camps at Bear Mountain and Fire Island for the benefit of convalescent service men and other former soldiers and sailors who are taking vocational training in New York City.

"Healer" Attracting Crowds in New Orleans.—"Brother Isaiah," a kindling peddler, said to be a Canadian, 73 years old, who lives on a ramshackle houseboat off the Mississippi River levee at New Orleans, is attracting crowds of halt, maimed and blind, as well as the perfectly healthy, desirous of testing or witnessing his alleged cures by the laying on of hands. State and municipal authorities have refused to disturb the peddler. Dr. Oscar F. Dowling, President of the State Board of Health, said no legal action could be taken against the "healer," because he was "accepting no money, prescribing no medicines and violating none of the rules of religious practice."

Hospital Society Seeks Literature.—In its forty-fifth annual report, the Hospital Book and Newspaper Society reports the distribution, between December 5 and April 19, of 670 books, 10,225 magazines, and 13,720 illustrated and weekly papers. The society was originally organized to provide reading matter to inmates of hospitals, prisons, and other institutions in New York City. Its activities have been extended to the sparsely populated sections of the South and West. The Society reports especial need of juvenile literature, children's books, magazines and papers, novels of wholesome character and school books and histories.

Self-Administration of Drugs and the Law.—In a report dealing with the classification, treatment, and general condition of drug addicts in New York City, Dr. S. Dana Hubbard, Acting Director of Public Health Education of the Health Department, holds that tht self-administration of narcotics should be forbidden by law. He deprecates the practice of some physicians of prescribing drugs for addicts to be self-administered. The clinic for drug addicts, which was opened by the Health Department following the arrest of a number of physicians for violation of the narcotic law, thus cutting off the source of supply of drugs from addicts, was found, according to the report, to possess all the objectionable features characteristic of the so-called "ambulatory" treatment, as practised by the trafficking physicians.

Course in Radiology.—The Post-Graduate Medical School and Hospital announces the inauguration of a course in radiology, covering all the modern developments in the use of radium.

"Department of Public Welfare."—Bird S. Coler, Commissioner of Charities, New York City, has started executive machinery moving toward changing the name of the Charities Department to the Department of Public Welfare. The Commissioner holds that women about to become mothers whose husbands cannot afford to pay for

high-priced specialists and who are finding accommodations in hospitals under his supervision, will be far less embarrassed in making application for such accommodations under the new designation.

Women "Railroaded" to Insane Asylum Released.—Two elderly spinsters, sisters, claiming to have been kidnapped and "railroaded" to the Kings Park State Hospital, at Kings Park, L. I., in June, 1910, were released recently through the intervention of one of the women attendants. The much needed thorough investigation has been called for to ascertain the facts in the case and to discover how it is possible, even in the event of incarceration without proper commitment procedure, for persons thus illegally committed to be detained for ten years.

Asylum Inquiry in Jersey.—Burdette G. Lewis, State Commissioner of Institutions and Agencies of New Jersey, at the instigation of Governor Edwards, will investigate charges of brutality at the State Village for Epileptics at Skillman.

Drive for Maternity Nurses. — The Visiting Nurse Service of New York City is conducting a city-wide campaign for a fund of $1,000,000. Additional day and night maternity centers are to be established with part of the fund. The center now maintained at 234 East Seventy-second Street is taxed to the utmost.

Plague-Control in Esthonia. — The Esthonian Government has given the American Red Cross Commission, under command of Lieut.-Colonel Edward Ryan of Scranton, Pa., authority to adopt any measures, political or economic, which may be deemed necessary to stamp out the epidemic of typhus. The country has been put under the strictest quarantine rules. Travel from one point to another by all persons not provided with a Red Cross permit is forbidden, and no Esthonian living in an infected region can board a train or leave the limits of his home district without permission of the American authorities.

Child Relief in Hungary.—Since August, 1919, American child relief workers in Hungary have distributed 170 tons of sugar, 414 tons of milk, 290 tons of peas, 146 tons of fats, 37 tons of soap, and 613 tons of flour. One meal daily is being given to 105,000 children by this American relief organization.

Smith College Relief Unit Decorated. — The French Government has bestowed the silver medal of "Reconnaissance Française" on the Smith College Relief Unit for work among the civil population in the retreat from Montdidier.

Church Hospitals for Incurables.—The Interchurch World Movement proposes to establish at least four hospitals for incurables to be conducted under church control, one each in Massachusetts, Missouri, Ohio, and Virginia.

Cracow University Honors Hoover.—The degree of Honorary Doctor of Medicine has been conferred upon Herbert Hoover by Cracow University for services rendered to Poland.

Dr. Walter H. Brown has been appointed Associate Director of the Department of Health Service in the American Red Cross with headquarters at Washington, D. C. Dr. Brown is a graduate of Jefferson Medical College, 1906, and of the School for Health Officers of the Massachusetts Institute of Technology, and Harvard University in 1915. During the past three years he has served as Health Commissioner in Bridgeport, Connecticut, as a member of the Connecticut State Board of Health, and as a lecturer on public health at Yale University.

Dr. George A. Blumer has resigned as dean of the Yale School of Medicine. The resignation has been accepted, to take effect at the close of the present academic year. Dr. Blumer has served as dean since 1910, and as professor of medicine since 1907.

Dr. George L. Richards of Fall River, Mass., has returned after ten months of service in the interior of Turkey.

Obituary Notes.—Dr. Fred Swartzlander, veteran of the Civil War and practising physician until two years ago, died at his home in Omaha, Neb., Feb. 22, at the age of 72. Born in Pennsylvania, he enlisted in the Sixth Pennsylvania Cavalry at the age of 17,2 serving throughout the war. He was graduated from Jefferson Medical College, Philadelphia, in 1872, going to Nebraska in 1887.

Dr. Albert F. Koetter of St. Louis, Mo., died February 28, after a prolonged illness, at the age of 49. He was graduated from Missouri Medical College in 1892, specializing in oto-laryngology. He was a member of the American Medical Association, the Oto-Laryngological Section of the St. Louis Medical Society, and other organizations.

Dr. Hosea B. Burnham of Manchester, N. H., died February 29, after a prolonged illness. Dr. Burnham was born in old Chester, now Auburn, in 1829, and was graduated from Vermont Medical College in 1853. He was active in professional and civic matters in his state.

Dr. Charles H. Wagner of Minneapolis, Minn., died March 1, after a long illness. He was 67 years of age, and was graduated from Cleveland University of Medicine and Surgery in 1873. He had practised in Minneapolis twenty years.

Dr. William R. Buchanan of Washington, D. C., died March 5, at the age of 50. He was graduated from the Hahnemann Medical College and Hospital of Philadelphia in 1902, specializing in pediatrics.

Dr. Henry Carey of New York City, died March 6. He was graduated from the Eclectic Medical College of the City of New York in 1894, and was for fifteen years a member of the Department of Charities as examining physician for tuberculosis.

Dr. Leonard F. Schmauss of Alexandria, Ind., was killed February 27, when an automobile in which he was riding was struck by a passenger train. Dr. Schmauss, who was fifty-eight years of age, was graduated from Rush Medical College in 1897. He was a member of the American Medical Association, and was actively identified with the Madison County Medical Association and other local organizations.

Dr. Sheldon B. Hewitt of Girard, Kan., died February 26, at the age of 42. He was graduated from the University Medical College, Kansas City, Mo., in 1904, and was a member of the American Medical Association and state and local bodies.

Dr. Edward Melville Whitney of New Bed-

ford, Mass., died after an illness of two years, on February 27, at the age of 64. He was graduated from Jefferson Medical College, Philadelphia, in 1879, specializing in ophthalmology. He was a member of the American Medical Association and of other societies.

Dr. PELEG FRANCIS WALKER of Providence, R. I., died suddenly from cardiac disease February 27, at the age of 61. He was graduated from the Boston University School of Medicine in 1881, and had been a member of the Providence school committee for thirty years.

Dr. JOHN B. DRAPER of Oswego, Kan., died recently at the age of 77. He was graduated from Rush Medical College in 1868. At one time Dr. Draper was surgeon of the State Soldiers' Home at Fort Dodge, Kan.

Correspondence.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, March 13, 1920.

The Reward of Scientific Medical Research.—In a previous letter attention was drawn to a proposition advanced by several leading scientific medical men that medical research should be compensated by the State. If not adequately compensated, at least, that men who as the result of brilliant and painstaking investigations had benefited the race, should receive certain pecuniary acknowledgment that their efforts on behalf of their fellow men were, to some extent, appreciated. Of course, as a rule, the men who make great scientific discoveries, medical or otherwise, reap little advantage therefrom. They are generally exploited by shrewder or more cunning individuals who take the lion's share of the profits and a good deal of the fame. However, a movement is afoot at the present time in Great Britain to remedy in some degree the existing state of affairs and not only to give honor where honor is due, but to give some tangible material proof that virtue is not necessarily solely its own reward. The other day a deputation of medical men, introduced by Sir Watson Cheyne, M.P., and including among its members Sir Clifford Allbutt and Sir Ronald Rose, waited upon Mr. Balfour to urge upon the Government a proposal for the granting of awards or pensions to persons making medical or other scientific discoveries of general benefit to humanity. As mentioned in a previous letter the method suggested is the annual voting of £20,000 to be distributed in pensions, some of £1,000 a year, others of £500.

In Great Britain, this question is thrown into an especially bright light just now, at a time when large sums of money are being awarded to those who have assisted the country's military effort by inventions which have been used to good effect by the army and naval authorities. It seems a curious commentary on human reasoning, exposing the fallacy of it in a marked manner, when an invention to destroy life will be recompensed to an unlimited extent, while a discovery in healing science which will save far more lives than the most deadly device of war could destroy is not considered worthy of any material recognition. The circumstances in which the greater part of British research is carried on are deplorable or rather disgraceful.

In medicine, for instance, much of the most valuable research work here has been done by men in practice, who obviously have had to contend with obstacles of every kind. Even the man who is paid for research work receives the veriest pittance in most cases. The story of British medical research is generally speaking a pitiful one, and indeed in most countries the path of the scientific investigator has been rough and stony. In America private generosity has rendered the lot of the research worker less strewn with thorns. The American millionaire has given with open-handed lavishness money to promote medical research. In this country, as a rule, the millionaire seems chary of devoting any considerable amount of his gains to further the research for means to fight disease successfully. As Sir Ronald has probably said truly, a medical man who gave to the world the long-sought cure for cancer would get nothing for his pains from his own people. Yet of the British people alone, statistics have stated that 35,000 die from cancer every year upon the average. Money spent on medical research is good sound business, possibly the cheapest national investment. If the comparatively small sum asked of the British Government for pensioning those qualified for medical research is granted, it would provide a great stimulus to the prosecution of research of every kind. It is to be hoped that the proposal of Sir Watson Cheyne and his colleagues will be recognized by the Government as reasonable and will be acted upon forthwith.

The Position of the British Hospitals—It is becoming more evident each day that the position of British hospitals is unsatisfactory and in some cases desperate. All kinds of projects have been set afloat to raise money to enable them to carry on, but none of these has been markedly successful. The cost of up-keep has risen immensely and money has not been forthcoming in nearly sufficient amounts to meet this increased cost. As said before, the financial outlook of British hospitals is very gloomy. Their revenues are obtained from three sources, in the vast majority of instances—endowments, voluntary contributions and workmen's collections—all of which are wholly inadequate at the present juncture. Quite a few make some income from "paying" wards for a limited class of patients, but up to the present time paying patients are negligible factors in the maintenance of hospitals. Indeed taking all facts into consideration it seems fairly plain that there are only two courses open to the hospitals. These are State aid, which signifies the abandonment of the voluntary principle, which by the way the hospitals themselves do not desire, nor is the Government capable now of taking over the hospitals, or the crisis must be met by emergency measures. State aid means State control, and the establishment of bureaucratic supervision is abhorrent to the Britisher. The pay system does not appear to be in favor in Great Britain. Why, it is hard to say.

At the same time, it seems to be the only practicable way out of the difficulty and public opinion is bearing somewhat towards its modified adoption. Many London hospitals are considering schemes of payments by patients. It has been decided in some institutions that in future inpatients shall be asked to pay for their own food and in one or two London hospitals out-patients are asked to pay a small fee for medical treatment. So far as British hospitals are concerned they are mainly devoted to the benefit of the working class and that working class is, owing to its greatly increased earnings, better able to support the hospitals than in pre-war days. The middle class, which is now the poor class, cannot claim the benefits of the hospital. Does not this seem an altogether anomalous situation? And would it not be to the advantage of all if a pay or modified pay system were introduced? Sir George Newman, the chief medical advised to the Ministry of Health, who probably has as thorough a grasp of the subject as any man in Great Britain, has pointed out that there is no general hospital system in Great Britain and that matters would be greatly bettered if organization were introduced. A complete and satisfactory hospital system cannot be provided for many years but a beginning may be made. The writer holds the view that a pay or modified pay system will be introduced and he further thinks that, on the whole, it will be the most sensible solution of the hospital problem.

New Health Insurance Bill.—Dr. Addison, the British Minister of Health, introduced into the House of Commons on March 1 the bill prepared by the Ministry of Health to amend the acts relating to national health insurance. As the first reading was purely formal, no explanation was given of the provisions of the measure, which, affecting as they do many millions of people are of great interest. The bill proposes to increase the rate of sickness benefit for men to 15 shillings per week and for women to 12 shillings per week. Disablement benefit is to be raised to 7 shillings and sixpence, and maternity to £2. As regards the provision made for sanatorium treatment, the Ministry of Health will ask Parliament to agree to its complete removal from the act, as it is desired to deal with tuberculosis as a whole. The bill not only provides for higher rates of benefit, but also for increased contributions, and for better remuneration for panel doctors.

The Joel Chair of Physics.—Physics, especially in the field of electricity plays an ever increasingly greater rôle in medical science. The new Chair of Physics which was established recently at the Middlesex Hospital School by the munificence of Mr. S. B. and Mr. J. B. Joel has now been filled by the appointment of Dr. Sidney Russ, D.Sc. as first occupant. The work of the new professorship, which is the first solid recognition of the importance of physics in regard to medicine, is expected to achieve great things. Dr. Russ was educated at University College, London, and was demonstrator in physics at Manchester University from 1906 to 1910. He was made physicist to Middlesex Hospital in 1913. He is president of the Röntgen Society and since last October has been lecturer in physics at Middlesex Hospital School. At the early age of forty, he has already made his name by his contributions to medical physics.

The Middlesex Hospital Chair of Pathology.—Dr. James McIntosh, M.D., Ch.B. has been appointed to the University Chair of Pathology at the Middlesex Hospital. He was educated at the Pasteur Institute in Paris, as well as at Aberdeen. He has been assistant in the Bacteriological Department of the London Hospital since 1910. During the war he carried out valuable researches at the Royal Herbert Military Hospital, Woolrich, on cerebro-spinal fever and on gas gangrene at the London Hospital. For the past nine months he has been a full time investigator on the staff of the Medical Research Committee.

Appointment of Regius Professor of Medicine at Oxford University.—The King has been pleased to approve the appoint of Sir Archibald Edward Garrod, K.C.M.G., M.D., to be regius professor of medicine in the University of Oxford, in the room of the late Sir William Osler, Bt., M.D. Sir A. E. Garrod is a graduate of Oxford University and physician to St. Bartholomew's Hospital, and his name is well known among the members of the English-speaking medical profession for his investigations as to gout.

London's Birth and Death Figures.—A comparison of the births and deaths in London in the eighth week of the present year with those of the eighth week of last year yields some striking results. There were more than twice more births, and there were little more than half of the deaths. The figures as given in the Registrar-General's weekly return issued on March 3, were: Eighth week, 1919, births, 1,201; deaths, 2,654. Eighth week, 1920, births, 2,643; deaths, 1,425. There were more births in the eighth week of 1920 than in any corresponding week for the past eleven years. In the 96 great towns of England and Wales, the figures were likewise highly satisfactory, from the point of view of repairing the ravages made by the war and influenza. During the week the total number of births in the civilian population of these centers was 10,644, and of deaths 5,614, a birth-rate of 30 and a death-rate of 17.7 per 1,000. A curious feature of the figures is that in the last week of 1919 London had only 1,318 births and that in the first week of this year there were 3,308, and the tables suggest no reason for the difference. Nor is it evident why the eighth week of 1919 was so deadly. In that week 1,022 more people died in London than the average for the past eleven years. In the eighth week of 1920 the deaths, with an increasing population were 196 below the average. In the 96 great towns of England and Wales there were 178 deaths from influenza in the eighth week of 1920, against 161 the week before, and 77 in the first week of December.

Plague and Influenza.—Broquet has recently studied in person the Manchurian plague and the bacteriology alone is sufficient for complete differentiation. Antiplague serum is of value in grippe only because it antagonizes the leucopenia and it shares this property with other antisera. Grippe is, however, not plague. —*Gazette des Hôpitaux.*

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. Malignancy and Radiation. A study of the Relation of the Structure of Cancer Tissue to Radiation. Frederick Bryant. Discussion by Edward Reynolds.
2. Caesarean Section. Nathaniel W. Emerson.
3. The Next Step in the Campaign for Infant Welfare. The Education of the Women of the Nation for Motherhood. Isaac W. Brewer.

1. Malignancy and Radiation.—Frederick Bryant, in this discussion of the relation of the structure of cancer tissue to radiation, first reviews the cancer problem from the point of view of what is and is not known regarding the causation of the disease, accepting the platform of the American Society for the Control of Cancer as employed in its campaign of education. In the discussion of the action of radiation on cancer tissue the writer combines his own observations with those of the leading American, English and French radiopathologists, giving four illustrative sections of an epithelioma of the cervix uteri in which the retrogressive processes are followed by a series of successive biopsies. These show the rapidly growing malignant epithelioma in the successive stages of complete retrogression, under the influence of radiation, into dense connective tissue. The writer does not accept the view that this stimulation of connective tissue presses out or shuts off the cancer cells by constricting bands, because the first changes are noted, as in the ameba, in the cell itself, or, more accurately, in the nucleus of the cell. The connective tissue appears later. He holds the view that radiation acts upon the newly forming cells which are of an embryonic type and therefore weaklings, less hardy than normal cells; that at the same time it exerts a destructive influence upon the fresh sources of blood supply which partake of the same immature nature; that while connective tissue proliferation is undoubtedly stimulated to some extent, its chief advent is in response to nature's call for repair processes to replace the destroyed cells. Such, in a general way, is the accepted view of the action of radiation on morbid tissue, provided the malignant mass is rich in cellular elements and rapidly procreating; that the source of radiation can be brought into adequate contact, and that its intensity is wisely regulated. Unfortunately, this is not the whole story, for many perils and misgivings beset the path of the radiotherapist in his attempt to bring about the utter destruction of the malignant lesion. Various factors must be considered. Variations of type and locality of the malignant growth are handicaps. The condition of the tissues surrounding the malignant area must be taken into consideration. Every factor which reduces bodily vigor or resistance speeds on the invasion. The age of the growth is another important consideration, for the older it is the less likely it is to submit to treatment, for the cancer cells have long since ceased to execute the reproductive process. In the radiation of these aged and self-limiting lesions there is grave danger of breaking down nature's feeble yet sufficient resistance and thereby give aid rather than battle to the old but comparatively harmless lesion. An infection of the tumor tissue under treatment is a complication much to be dreaded. It has been shown that radiation, acting upon the nucleus, inhibits the reproductive function of the malignant cell. Therefore, in operable cases, its use is advised just prior to the operation to render the tumor less malignant. This radiation should include all possible lines of metastasis to catch any glands already invaded and on beyond to reach the innocent lymphatics that they may become sclerosed and thereby rendered obstructive to any further invasion. After the thorough removal of the malignant mass, the radiations are again advised, at stated intervals, to accomplish the destruction of any scattering cancer cells which may have been left. The writer believes that this procedure, in operable cases, will result in lessening the number of recurrences, and greatly add to the permanence of surgical work. For inoperable cases, the radiations are advised to prolong life, to lessen pain, to check hemorrhage and nauseous discharges. In a small percentage (seven) it has reclaimed the case to operability or permanent relief. The author of the paper is in accord with those who hold that mastery of all the various forms of radiation is the first essential in the treatment of the various forms of malignancy.

9. The Treatment of Tuberculosis in Experimental Animals. (Concluded.) Benjamin S. Paschall.

8. Use of Relaxation in Hypertensive States.—Edmund Jacobson presents a method for the treatment of irritability, excitement and insomnia suggested in part by experiments at Harvard and Cornell universities about ten years ago, which are now being continued at the University of Chicago. The method has been in clinical use for about two years. In principle it is simple; in practice, however, it rests upon so many observations and details in dealing with each individual patient that the present attempt is to give a condensed introductory sketch rather than a complete report. The method described makes use of relaxation—motor treatment of nervousness. The particular form of relaxation required is intensive and progressive. It is assumed that a detailed history has been taken, thorough physical and laboratory examination made, and that proper treatment is being given in the way of surgery and drugs or hygienic measures or psychotherapy. The patient is first shown general relaxation of his whole body, whether his complaint is nervous excitability or insomnia or both. He lies down quietly in a room free from disturbance and begins with the right arm, which he flexes tensely against resistance made by the physician. He is directed to note the sensations from the flexor muscles of his right arm, the position of which is indicated to him. Then he relaxes his arm until these sensations disappear. For a single attempt at this, five to ten minutes are allowed. Drill is given until he is able to note the dwindling sensations many minutes after he has begun to relax, and until it is clear that he is using these sensations as a guide to relaxing. It is often useful to make clear that at this stage extreme relaxation of a part may require at least fifteen minutes of progressive inactivity. After he has been fairly successful, he extends the forearm against resistance, noting the sensations, then relaxes both flexors and extensors. Practice is next given with flexion and then with extension of the hand. Finally the patient is instructed to relax the right arm completely, "further and further each minute" until no feeling of tenseness remains. In this way the patient practises at relaxing one muscle group after another. As he begins to relax a new group he continues at the same time to relax all previous groups, until finally he relaxes the entire body at one time. The physician watches closely for signs of failure or progress, makes occasional tests and gives simple directions in a quiet way. An excited patient may spontaneously quiet down early in the practice, or it may be necessary to discourage him from speaking and have him close his eyes. The physician estimates the degree of relaxation chiefly by the apparent limpness and by the absence even of the slightest movements during a prolonged time; but rarely also by palpating the muscles or shaking a limb. Unnecessary speech or restless movements of any part whatsoever are signs that a particular part is not being progressively relaxed. Having learned to relax generally at will the patient has at his disposal a means of overcoming a spell of nervousness. Irritability, impulsiveness and excitement may be overcome, in the opinion of the author of the paper, by the maintenance of a relatively relaxed condition whenever one is sitting up or walking, the patient keeping only such muscles active as are needed to maintain his position.

3. Botulism: Preliminary Report of a Study of the Antitoxin of Bacillus Botulinus. Dickson and Howitt report experiments performed during 1917-1918, publication of which they had planned to delay until further experimental data could be obtained concerning certain unsettled points. On account, however, of the present interest in the subject, and because of the expression of various theories and speculations concerning the value of the botulinus antitoxin as a therapeutic agent, they offer this preliminary report. The antitoxin used in their experiments was obtained by inoculating Goats 1, 2 and 3 with Strains III, IV and VI, respectively, of their strains of *B. botulinus* over a period of several months. They were unable to follow out any previously determined plan for inoculating, as the goats reacted so differently to inoculation that they were forced to regulate the dosage and interval by the condition of each animal at the time. The potency of their three antitoxins, and the fact that they will neutralize the effect of the toxin when multiple proportions of the test dose of toxin and of antitoxin equivalent are mixed *in vitro* and injected into animals, are shown in tables. From these it is noted that the potency of the antitoxins may be defined as approximately 3,000, 5,000 and 600 for Strains III, IV and VI, respectively, the number indicating the respective antitoxin equivalents in 1 c.c. of serum, as tested against one test dose of its homologous toxin. The writers investigated the toxins of seven strains of *B. botulinus*, six of them strains that were recovered in their laboratory from various home-canned vegetables and fruits that had caused outbreaks of food poisoning on the Pacific Coast, and one that was recovered by Niven from cheese in New York State. From their experiments the following conclusions are drawn: 1. A true antitoxin may be prepared for the toxin of *Bacillus botulinus*. 2. There are at least two types of *B. Botulinus*, which are distinct so far as their toxin-antitoxin relationships are concerned. 3. Experiments show that in the laboratory the antitoxin may protect against the action of the toxin for at least twenty-four hours after the administration of one test dose of toxin, but that the effectiveness is, to a certain extent at least, dependent on the amount of toxin injected. 4. For therapeutic administration a polyvalent antitoxin should be employed, and it should be given in large amounts and intravenously.

6. Encephalitis Lethargica in Pregnancy.—Margaret Schulze reports in detail a case of encephalitis lethargica which occurred in a pregnant woman of thirty-five. In a review of the recent literature she found only seven other cases occurring in pregnant women. These are analyzed. There was no history of influenza in her own case. The patient, after getting up and walking about the bed without permission, suddenly developed symptoms of pulmonary embolism and died in twenty minutes, twenty-six days after delivery. Postmortem examination revealed thrombosis of both femoral veins and extensive bilateral pulmonary emboli, which occluded almost the entire pulmonary circulation. Microscopically the brain was practically normal except for a few punctate hemorrhages on cut section in the region of the midbrain. The cerebrospinal fluid was normal in appearance and amount. Microscopic examination revealed the characteristic changes of lethargic encephalitis. There was congestion and slight round cell infiltration of the leptomeninges. There were marked perivascular infiltration and a few small hemorrhages about the vessels, especially of the midbrain and pons. There was no degeneration of the nerve cells. The medulla showed much less marked changes; the cerebral cortex was normal.

6. Influenzal Pneumonia: The Intravenous Injection of Hydrogen Peroxide.—Oliver and Murphy used a strength of two ounces of hydrogen peroxide in eight ounces of normal saline solution, three ounces of hydrogen peroxide being used in one case without ill effect. Fifteen minutes was allowed for transfusion and this was checked temporarily every four minutes, or whenever large bubbles of oxygen appeared in the cannula, or if the patient became at all restless. Small bubbles entering the vein did not appear to do any harm. In one case the patient struggled so violently in his delirium that the cannula slipped out and the distal ligature came off. On pressing the vein above two distinct streams could be seen to issue from the wound, the one above bright red and frothing, the other deep blue. From their experience in twenty-five cases the writers hold that hydrogen peroxide can be given intravenously without gas embolism being produced. The anoxemia is often markedly benefited, and the toxemia appears to be overcome in many cases. The mortality (48 per cent.) compares very favorably, they believe, with the 80 per cent. in similar cases not so treated, and more so when it is remembered that they treated only the most severe and apparently hopeless patients.

7. Anæsthesia in Nose and Throat Operations.—Felix Rood endeavors to uphold the safety of ether; the danger of chloroform, as demonstrated, apart from all scientific considerations, by the records of the daily press; the improvements in the methods of administering ether so that the congestion, cyanosis, and salivation of other days have given place to an anesthesia which has all the merits and none of the dangers of chloroform; and the gradual evolution of operative surgery of the mouth, from the rapid operation on coughing patient towards the ideal of a quiet patient free from all risk of suffocation, combined with every facility for a thorough and deliberate operation.

2. Tumors Complicating Pregnancy, Labor and the Puerperium.—Herbert R. Spencer discusses in this lecture, the second of the series, the first of which was reviewed in the MEDICAL RECORD for March 13, ovarian tumors complicating pregnancy, labor and the puerperium, giving details of 55 cases. The ages of the patients varied from 20 to 43 years, the average being 30. Nine patients were nulliparæ at the time the ovarian tumor was present, nine had had five or more

children, one had had nine, and three ten. Altogether the 55 patients had had 150 children, an average of nearly three, before the tumors were removed. Information as to the occurrence of abortion was not noted in 7 cases; the remaining 48 women had had 125 children and 33 abortions. The proportion of abortions to pregnancies was therefore 26.5 per cent. Of the 55 cases, 40 were not operated on during pregnancy and 15 were. In only 5 of those not operated on during pregnancy, or 12.5 per cent., did abortion occur in the pregnancy preceding ovariotomy. In 5 out of 6 cases in which both ovaries were affected abortion did not occur; in the sixth case the notes leave the matter in doubt. Of the 15 cases operated on during pregnancy 4 aborted (26.6 per cent.). In 10 of the 15 cases operated on (66.6 per cent.) the pregnancy continued and living children were born, but one died shortly after. As 3 of the patients were operated on at term, when the question of abortion does not arise, the true abortion rate for patients operated on before the child is viable is in this series 4 out of 12 cases (33.3 per cent.). The tumor was cystadenomatous in 33 cases (60 per cent.), dermoid in 15 (27.2 per cent.), ovarian fibroid in 3 (5.4 per cent.), and "parovarian" in 6 (10.9 per cent.). Torsion of the pedicle was found 12 times in cystadenomatous tumors, 5 times in dermoid tumors, and once among the "parovarian" tumors, a total of 18 (32.7 per cent.). The tumor was situated in the right ovary in 23 cases, in the left ovary in 18 cases, in both ovaries in 8 cases, in the right parovarium in 4 cases, in the left parovarium in one case, in the left parovarium and in the right ovary in one case. The tumor was incarcerated in the pelvis in 5 cases. In one case the tumor was mistaken for a uterine fibroid; cesarean section was performed, with a successful result to the mother and child. In the other 4, which were all dermoids, the value of treating the obstructing tumor either by pushing it up out of the pelvis or removing it by operation was illustrated. The danger of delivering the child while an ovarian tumor is in the pelvis is illustrated by a specimen exhibited before the Obstetrical Society in 1898, which showed rupture during version after an attempt at delivery by forceps, with a fatal result to the mother. Adhesions were found in 26 cases (47.2 per cent.). All the suppurating cases were adherent. Dermoid tumors in which the pedicle was not twisted were free from adhesions except in two instances. There appears to be no evidence in the cases observed of specially rapid growth of the tumor during pregnancy. Of the 15 patients subjected to ovariotomy, one died. The children (in one case twins) were born alive in 11 cases, but one of the children died soon after birth; 4 patients aborted; thus, in 5 out of 15 cases the child was lost. The mortality rate for the children therefore was 33.3 per cent.; the abortion rate was 26.5 per cent., or, more correctly, 33.3 per cent. In four other cases seen by the lecturer during pregnancy, and operated on, the mothers recovered and the children survived. In the 40 cases not operated during pregnancy all the mothers recovered from the labor or abortion. In 29 cases (out of 37 in which the fate of the child is given) the child was born alive; in 4 cases the child died as a result of difficult delivery by forceps or version. In 4 (possibly in 5) out of the 40 cases abortion occurred. The mortality rate for the children is 8 out of 37 (21.6 per cent.). The abortion rate is 10 per cent., or possibly 12.5 per cent. The scheme of treatment, first published in 1909 in the *Transactions of the American Gynecological Society*, is given, with slight verbal alterations.

3. The Effects of Deficient Dietaries on Monkeys.—Robert McCarrison, of the Pasteur Institute of S. India, Coonoor, records experiments made on monkeys (*Macacus sinicus*) captured from the local jungles. Ten were fed on autoclaved rice, and four on autoclaved rice *plus* butter. Twelve monkeys, fed on rice, bananas, monkey-nuts, milk, onions, and bread, served as controls. The rice (milled) was autoclaved at a temperature of 130° C. for an hour and a half. An exclusive diet of rice so autoclaved, the writer holds, may be considered to be wholly deprived of accessory food factors of all three classes; it is excessively rich in starch and deficient in proteins, fats, and salts. A dietary of autoclaved rice *plus* butter is lacking in accessory food factors of the "B" and "C" classes, while it is ill balanced with respect to proteins, carbohydrates, and salts. The results of these experiments on monkeys confirm those previously recorded by McCarrison in the case of pigeons fed on similar food. He considers them applicable in kind, if not in degree, to human beings subsisting, as frequently happens, on food similar in composition to that on which the monkeys were fed. From his observations he forms the following conclusions: 1. Dietaries which are deficient in vitamines and in protein, and at the same time excessively rich in starch or in fat, or in both, are potent sources of disease, and especially of gastro-intestinal disease. 2. An excess of fat, in association with deficiency of "B-vitamine" and protein and superabundance of starch, is peculiarly harmful to the organism. 3. Certain dietetic deficiencies greatly favor the invasion of the blood and tissues by bacteria; especially is this the case when deficiency of vitamines and proteins is associated with an excessive intake of starch. 4. Since life cannot be sustained in the monkey, *Macacus sinicus*, for much longer than 100 days on a dietary almost wholly devoid of "B-vitamine," it would appear that complete absence of this vitamine from the food is of less practical importance from the point of view of the production of disease in human beings than its subminimal supply. Complete deprivation of "B-vitamine," especially if there be also imperfect balance in other essential requisites of the food, will lead to rapid dissolution and death; subminimal supply of this vitamine will lead, in like circumstances, to slow dissolution and disease. 5. The results recorded may afford some explanation of the genesis of that great mass of ill defined gastrointestinal disorder and vague ill health which forms so high a proportion of human ailments at the present day.

1. The Physical Signs of Foreign Bodies in the Bronchi.—Thomas McCrae calls attention to the fact that there may be no disturbance at the time of entrance of a foreign body and no suggestion in the history of such a happening. Certain signs are of value, especially decreased expansion on the affected side, the presence of very fine râles and the "asthmatoid wheeze." Some foreign bodies, such as a peanut, set up a very acute general process which is fairly distinctive. Other structures, such as metallic objects, cause permanent changes, usually in a lower lobe. The chief errors in diagnosis are to mistake the signs for those of pneumonia in the early stages and in the acute cases, and for tuberculosis after the body has been present for some time.

7. The Dangers of Ascariasis.—Bowman Corning Crowell holds that the wide territory covered by the *ascaris*, the number of the population infested by it and the harmful results attending its presence entitle

it to more respectiful attention than is usually accorded it. In practically all places, if not in all, in which examinations are made for parasitic infections, it is found that the *ascaris* is the parasite most frequently encountered. It is also one of the worms that is most easy of recognition, and for that reason very little difficulty attends the diagnosis. Perhaps these facts, he says, have helped to distract the interest of the physician from this homely worm. The average physician who has had any experience in tropical countries where the *ascaris* abounds will say that the treatment of ascariasis is easy, which is probably true in the vast majority of cases, and that its harmful effects are slight anyway, which the writer declares is decidedly not true. He thinks the word of the pathologist is heard only too infrequently on this subject, for which reason he records some of his experiences with this worm as seen in the autopsy room during several years in Manila. The experience led him to look upon the *ascaris* with more respect and fear. A simple examination of the hospital records of tropical countries will show what a large number of cases are admitted to these hospitals for ascariasis alone, aside from those in which ascariasis is found complicating other diseases which are usually considered more serious. If this be followed by an examination of the records of the associated morgues, with their never-ending list of surprises, the case against the *ascaris* will be strengthened. Crowell discusses the pathological effects of the *ascaris* under the following classification: 1. Mechanical effects are prominent and certain from the *ascaris;* these may be exerted when the worm is in the intestine or in the course of its migrations. 2. As a carrier of infection the worm is also of importance in its migrations. Whether through its eggs it may prove a source of transmitting infection is not yet proved. 3. The larvæ cause a bronchopneumonia in experimental animals, and it is not improbable that they may do so in some cases in infants. 4. The presence of a harmful toxic substance is a source of danger and reflex nervous symptoms due either to mechanical or toxic irritation are also frequently encountered. These phenomena are considered in detail and illustrative cases cited. These worms may cause symptoms and even death through toxic, reflex, and mechanical effects either in the larval stage or while adult in the intestine or in the course of their migrations to other parts of the body. Cases of disease of the intestine or other parts may assume much more than their usual seriousness on account of the presence of these worms, and the accidents due to the migratory proclivities of the worm may cause fatal complications of simple surgical procedures that would otherwise have terminated happily. The writer believes that a thorough and systematic examination of the cases of ascariasis would bring to light many cases in the experience of others, and would prove that ascariasis possesses the importance which he has indicated.

La Gynécologie.

xviii, 6.

Ectropion of the Os Uteri.—Doleris, under the title "Errors of Therapeutics in Cervical Metritis," gives an illustrated account of this condition which was formerly spoken of as ulceration and improperly treated. He asks, "What is cervical ectropion?" replying that a long time was necessary to learn that it does not represent a loss of substance. The word should be employed in lieu also of erosion and vegetating or fungoid cervicitis, etc. It is a prolapse or hernia of the mucous lining of the cervical canal, due usually to laceration. It becomes altered as a result of friction or infection and gives rise to hypertrophy, whether of mucosa, glands or stroma of the cervix. But there is also a non-traumatic form which is seen in nulliparæ, independent of laceration. This may be temporary or permanent. The protrusion may be due to intense congestion or muscular spasm. This type may be infected, whether by saprophytes or the gonococcus or tubercle bacillus, and may likewise lead to hypertrophy. This non-traumatic type is common. A cause behind the factors above mentioned is a congenital condition, identical with that encountered at times in the new born. The condition is silent until puberty when congestion, spasm of the sphincter muscle of the os or infection acts as a determining cause. As a rule, the nontraumatic form is circular and when it is of the vegetating or hypertropic type may simulate a tumor. Outside the limits of the ectropion the mucosa of the portio may show an eroded areola and this, the author proposes to call an erosion, which term he also uses for other affections, such as herpetic excoriations. In other words, an erosion has nothing in common with an everted or hernial cervical mucosa, but occurs on the portio as a superficial loss of protective epithelium.

Le Progrès Médical.

February 7, 1920, xlviii, 6.

The Crisis in Acute Infectious Diseases.—Loeper recalls that the ancient crisis of a disease meant literally the "judgment" or that kind of behavior which enabled the medical man to judge of the outcome of the malady; the judgment formed might be in favor of or against the patient's survival. Modern writers, of course, do not use the term in this sense, for by crisis we mean only the turning point of the disease process. In a more technical sense crisis connotes the elimination of the *materies morbi* or its toxic products, which should be followed by recovery (in the absence of complications or permanent damage to some vital organ). This association of the crisis with elimination causes us to speak of critical diaphoresis, diuresis, and diarrhea; the latter being rather questionable and more apt to indicate a complication. Lysis is not antagonistic to crisis but is merely a deliberate form of the latter. The diaphoretic expression of a crisis is apt to precede the latter or usher it in, and bears a relation to defervescence. Our present knowledge ranks critical diuresis as much the more important of these phenomena, for there is a very definite elimination of solids in the first 24 hours—as much as 30 gms. of the chlorides and 60 gms. of urea at times. It has also been shown that the urine of the critical day is highly toxic; in fact a man can eliminate enough poisonous material in one day to kill a man of the same weight in 13 or 14 hours. According to the relative predominance we may speak of chloruric and proteinic crises. In typhoid the subject may eliminate during the critical period as much as 300 gms. of chlorides, or all that he has retained in the three weeks of the disease which precedes the crisis. In infectious icterus as much as 147 gms. of urea have been excreted on the critical day. There are many minor phenomena of interest in connection with the crisis, some associated with blood counts. In speaking again of the ancient idea of the crisis the author gives Hippocrates credit for the statement that the *vis medicatrix naturæ* causes the elimination of peccant humors, but this idea had disappeared completely in later centuries. In the XVIII century the crisis meant little more than the resumption of normal functions.

High Frequency and High Tension in the Treatment of Tuberculous Osteitis.—Without claiming to have cured all or even a majority of a series of cases of this affection observed over a term of years, Doumer of Lille reports at least four cures since 1912, his work naturally having been greatly interfered with by five years of warfare. The patients were all placed in an electrostatic field of powerful oscillations. The voltage was above 80,000 volts and the oscillations varied from 800,000 to 1,000,000 a second. The seances lasted ten minutes and the interval was daily or triweekly. Of the four definitely cured patients one has remained well for the past eight years, and the others for six and seven years respectively. The fourth, after apparent complete recovery, suffered a relapse or reinfection. The duration of actual treatment shows the greatest diversity, for while one cure was obtained in a few weeks, another patient was treated for eighteen months before recovery. The cases which were merely improved or still under treatment receive no discussion, but the author states frankly that in at least two cases the treatment was actually inert. Differences in result appear to be due to site, extent, character, and chronicity of the lesions, so that no law can be laid down for selection of cases. The more superficial the lesion the better the outlook.—*Bulletin de l'Academie de Médecine.*

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Fourteenth Annual Meeting, Held in New York City, March 23, 24 and 25, 1920.

HOUSE OF DELEGATES.

Monday, March 22, 1920.

THE PRESIDENT, DR. GRANT C. MADILL OF OGDENSBURG, IN THE CHAIR.

Annual Reports.—Report of the President.—Dr. GRANT C. MADILL of Ogdensburg submitted this report, in which he stated that during the past year he had attended the meetings, with two exceptions, of all the district branches and many meetings of the county societies, and that in addition to interesting scientific programs, the affairs of the State organization were discussed in a manner showing deep interest in the welfare of the profession. He found, however, that no systematic effort was made by the county organizations to increase the membership, and it was his opinion that the State organization should carry on a propaganda to urge all eligible physicians to join their respective county societies. Dr. Madill spoke of the loss the society and the profession had sustained in the death of Dr. Abraham Jacobi, who was president of the society in 1882, and of Dr. Floyd M. Crandall, who had served for three years as secretary of the organization and for several months as acting editor of the *Journal*. The most important event of the society during the year was the duty performed by the special committee appointed to study compulsory health insurance with special reference to its relationship to the medical profession. The subject had been studied from every angle and in an unbiased manner. The unanimous adoption of the majority report showed the feeling toward compulsory health insurance. The medical profession, after its deliberate study of compulsory health insurance, could not be accused by the proponents of bills of the type of the Davenport-Donohue bill of uninformed prejudice. Of the constructive recommendations of this committee the most important were the fifth and sixth. The Fifth: "Owing to the paucity of accurate and unimpeachable data collected by means of an unbiased investigation, your committee recommends that the Legislature of 1920 be requested to appropriate a sufficient sum of money for the use of the Health Department, and such other departments in association with it, as it requires, for the purpose of making a survey of the State of New York to determine the amount and character of illness in its economical relation to the commonwealth." Sixth: "If additional legislation is to be enacted, it should provide for a greater development of existing agencies for preventive medicine, together with the extension on a large scale of the present county and municipal functions for both preventive and remedial medicine, and it should make further provision for the inauguration of more widely extended utilization of the present institutional clinical facilities for the diagnosis and treatment of disease, in order to facilitate the access of the entire population of the State to modern methods in the practice of medicine." These recommendations and their adoption by the House of Delegates showed that the medical profession of the State of New York was willing and anxious to cooperate with the State in the betterment of public health. During the past year, organizations were formed outside of the State Society to carry on a propaganda in opposition to Compulsory Health Insurance. In order to oppose Compulsory Health Insurance the medical profession in many instances sought, by political means, to influence the public in electing the members of the Legislature. It was his belief that the activities of the State Society on questions pertaining to public health legislation, so far as the relationship of the profession to the public was concerned, should end with the dissemination of information on the subject in question and an expression of an opinion as to what, in the judgment of the profession, was best for the public. With the public thoroughly informed on questions of public health legislation, the medical profession would be in a position to exert greater influence in the Legislature for wholesome and efficient health measures, without resorting to methods savoring of political tactics and asking for class legislation. Dr. Madill suggested that there should be appointed a committee whose duty should be to disseminate, through the officers of the county societies, information pertaining to public health matters. This report also recommended the appointment of an executive secretary. It was pointed out that the extension of the activities of the society demanded increased labor on the part of the officers of the various standing and special committees; that the members of this society were mostly engaged in active practice of their profession, and that it was difficult at all times for them to give proper attention to the duties of their offices. At the special meeting of the House of Delegates, held in Albany December 22, 1919, it was moved, seconded, and carried "That the whole question relative to the establishment of a legislative bureau of information and the report of the special committee be postponed until the next annual meeting of the House of Delegates." This question was therefore to be acted on at this meeting. An executive secretary of the society could, in his opinion, perform the duties as director of the bureau, if such a bureau were established. The report further called attention to the fact that the present income of the society was not sufficient to enable it to carry on any increase in its activities. The small surplus in the hands of the treasurer and the imperative need of extra outlay would soon bring about an exhausted treasury. To economize by curtailing any of the present work of the society would, in his judgment, be bad policy. The work of the society should be expanded and not contracted. He therefore recommended that Article 7, Section 2 of the Constitution be amended to provide for an increase of $2 in the annual dues. He felt that such an increase, together with an aggressive campaign for new members, would provide sufficient income for the employment of an executive secretary and for carrying out the suggested broadening of activities. At the annual meeting of the society, in 1917, a resolution was adopted by the House of Delegates providing that a special committee be appointed to make a revised draft of the present workmen's compensation law, which revised bill should be submitted at the next annual meeting of the House of Delegates, or at a special meeting called for the purpose thereof. There was no record of a report from this committee at an annual or special meeting. He thought another committee should be appointed to consider this resolution.

The House went into a committee of the whole to consider the recommendation to appoint an executive secretary. After discussing the matter they reported that they approved of this step.

Report of the Secretary.—Dr. EDWARD LIVINGSTON HUNT of New York reported that on January 21, 1907, the membership of the State society was 5,857. To-day there was an increase of 2,714. During these thirteen years they had lost through deaths, registrations, and expulsions 1,919 members. During the last twelve years 6,813 new members had been admitted. There were at present 14,446 practising physicians in New York State, of which number only 8,738, or a little over 60 per cent., were members of the State society. This report recommended that a special committee be appointed whose function it should be to devise ways and means of increasing the membership. This report also called the attention of the delegates to an amendment to Section 1, Article 3 of the Constitution, providing for the annual election of a speaker and vice-speaker to the House of Delegates; in other words, it would give to the legislative body a competent and permanent presiding officer. Dr. Hunt thought this step would be progressive and practical; it would save time and tend toward greater harmony and more constructive legislation. This report also called attention to a proposed amendment to the constitution which provided that delegates should be apportioned among the constituent societies in proportion to their actual member-

ship, except that each constituent society should be entitled to at least one delegate. This amendment was based on actual membership and provided an equable and just representation. A new section had been added to the scientific work of the society. For the first time in many years there would be a section on neurology and psychiatry. This was established at the suggestion of Dr. Thomas W. Salmon. In conclusion, this report paid a tribute to Dr. Crandall.

Report of the Treasurer.—Dr. HARLOW BROOKS presented this report, which showed that it had been necessary during the year to draw to the extent of $1,889.10 on the $9,153 surplus of the society.

Report of the Committee on Scientific Work.—Dr. PARKER SYMS submitted this report which stated that the question of making clinics part of the program had been considered and thought not to be advisable, as it broke up the section idea. The question of holding joint sessions was discussed and it was the final decision of the committee that a limited number of joint sessions was desirable, especially if they were so conducted as to bring important subjects before the society in the form of symposiums.

Report of the Committee on Legislation.—Dr. J. RICHARD KEVIN of Brooklyn submitted this report, which, having been written early in the session of the Legislature, was a tentative one. The bill of predominant interest, the Compulsory Health Insurance bill, it was understood would be introduced for "educational purposes" only, since the proponents were aware that it would not pass the Senate or the Assembly this year. The best information suggested, however, that the proponents would continue their efforts to obtain either this bill or one equally obnoxious during this or some subsequent Legislature. The State Department of Health had provided this committee with a memorandum of a skeleton bill which authorized a county, city, or consolidated health district to create and maintain one or more centers and provide State aid therefor. The proposed bill had the following aims:

"1. To provide for the residents of rural districts, for industrial workers and all others in need of such service, scientific medical and surgical treatment, hospital and dispensary, facilities and nursing care, at a cost within their means, or, if necessary, free. 2. To assist the local medical practitioners by providing: (*a*) Facilities for accurate diagnosis by a coordinated group of specially qualified physicians and surgeons, both for hospital patients and for out-patients. (*b*) Consultations and advice as to treatment by medical and surgical experts. (*c*) Clinical, bacteriological and chemical laboratory service and *x*-ray facilities at moderate cost, or free when necessary. 3. To encourage and provide facilities for an annual medical examination to detect physical defects and disease and to discover conditions favorable to the development of disease, and to indicate methods of correcting the same. 4. To provide or aid in securing adequate school medical inspection and school nursing service. 5. To secure or aid in securing better enforcement of the Public Health Law and a more effective administration of public health activities within the area served. 6. To provide a Public Health Nursing Service adapted to and adequate for the community served. 7. To aid in securing the dissemination of information in regard to public health throughout the area served. 8. To aid in securing adequate compensation for medical and surgical care rendered in hospitals and clinics, in order that efficient service may be everywhere available. 9. To provide laboratories, group diagnosticians, consultants and hospital facilities in the smaller cities and rural districts. 10. To provide medical libraries, including books, pamphlets, periodicals, leaflets, exhibits, moving picture films, and kindred educational facilities, with halls for meetings if needed. 11. To provide hospital and other necessary resources for dealing promptly with epidemics. 12. To reduce illness and disability among the industrial workers of the State by providing prompt and accurate diagnosis and efficient treatment for sick and injured workers and the members of their families. 13. To coordinate public health activities within the district." It provided for a grant of sixty cents per day for every three patients maintained in any hospital operated as a part of a health center. It provided for new construction and equipment of hospitals, one-half the cost to be paid by the State, such payment not to exceed $750 per bed, and beds for the purpose of this provision to be in proportion not in excess of one to each 500 of the population. It provided for clinics and annual medical examinations. It provided for out-patient clinics equal to one-half of the initial cost of establishment, the amount to be paid by the State for this purpose, not to exceed $5,000 per clinic and twenty cents for each treatment in such clinic. It provided a grant of fifty cents for each free, comprehensive, annual medical examination made at the health center. It provided for a grant from the State of one-half of the annual cost of maintenance of laboratory of health center, the sum to be paid by the State not to exceed $3,000 per annum for each laboratory, and $1,500 toward the initial installation and equipment of such laboratory. The National Civic Federation, which was consistently and persistently opposed to Compulsory Health Insurance in any form, had evolved a constructive plan to be dealt with by the Legislature. It contended that the immediate problem for consideration was not that of insurance against sickness, but the larger and more important problem of the extent of illness and the methods for its prevention. It had presented to the Legislature of New York facts demonstrating the need for a sickness survey. When these bills were introduced and printed the Committee would give them study and make recommendations. The report then considered the narcotic question. It stated that the present law was very inefficient in its workings and they believed that most of the physicians in the State were a unit in suggesting that the present law should be modified, at least to the extent that it should harmonize with the Federal law. Of the bills introduced the Committee was most impressed by the one introduced by Senator Cotillo. The annual Chiropractic bill appeared this year just as it had done in the past and Senator Carroll had introduced a bill "to define and regulate drugless therapy. It legalized a large number of "pathies." The danger signal of this bill was the grouping together of the various cults which might solicit considerable strength. The Committee was of course vigorously opposing these bills. The Annual Registration bill had been introduced. It was endorsed by the Council last year and therefore had their support this year. They felt that, notwithstanding some objections, the effects that would be produced by the annual registration of physicians in clearing the ranks of all cults and fakirs more than offset any objections which prevailed against the bill.

Report of the Committee on Medical Economics.—Dr. HENRY LYLE WINTER submitted this report which showed that this committee had increased its field of work by studying several phases of medical practice and of medicine and medical education, as well as impending public health legislation. The two most important studies undertaken were a partially completed survey at Chelsea, N. Y., and a special study to determine the amount of sickness among wage earners in proportion to that among their dependents. The original survey showed that 28 per cent. of sick people were not receiving medical attention. While none of the figures were complete, the indications were that this group would be much reduced. About 70 per cent. of the people so far certified as sick and not receiving medical care were found to have adequate means for securing such care should they desire it. Two per cent. of this group stated that they were unable to obtain medical care because of isolation, although they were able to pay for it. After citing the details of the investigation to determine the amount of sickness among wage earners and their dependents, the report concluded that while there was no question but that the conditions at these mills were better than the average, and while the investigations covered a small group, the figures were such as to raise the question as to whether or not the demand for application of alleviating measures to employees was as great as the proponents of health insurance would lead us to believe. This committee had plans under consideration whereby the subject of public medicine would be studied under the following topics: Research work on heredity, prenatal care, post-partum care of the mother, infant hygiene, child hygiene, child labor, control of the hygiene of industry, personal hygiene, communicable diseases, so-

cial medicine. This report approved of the annual registration bill. It advised that the Society record itself as opposed to any further increase in educational requirements for medical college entrance. The report approved of a plan whereby permanent commissions should be established in each judicial district to which all questions affecting the mental status of any person accused of a crime should be referred. Whether questions of sanity or of responsibility arising in habeas corpus or certiorari proceedings should take the same course or not was a question upon which they had had insufficient legal advice. They further urged that where the commission of the crime was not in question the determination of a commission of the irresponsibility of the accused should be final; and that the accused should not be tried but should be committed by the court to the proper institution for the criminal insane. Continuing, the report discussed the question of post-graduate study. The benefits to be derived from post-graduate studies had never been questioned, but they were denied to a large number of the profession because of lack of time and opportunity. It was therefore suggested that a systematic scheme of post-graduate work be undertaken under the auspices of this Society. The following initial plan was offered for consideration: Under the direction of a special committee, or the Committee on Medical Economics, a program should be drawn up which would supply the best teachers of the profession to certain districts throughout the State, at least once, perhaps twice, a year. In detail, the plan included the selection of a sufficient number of centers to enable the attendance of every physician in the State. These centers should be preferably cities having hospital facilities for clinical work. Lectures and clinics covering some special branch of medicine or surgery should be held at these selected points, and continued over a sufficient period each year to enable comprehensive, though intensive, courses of study. The committee further recommended that the Society give its approval to the campaign for National Health Conservation which the United States Public Health Service had begun, and that the Society put itself on record as in favor of amending one phase of national prohibition, namely, the limitation of the quantity of distilled spirits which might be prescribed. Finally, this report recommended that inasmuch as several regulations had been enacted which affected the practice of medicine, and inasmuch as a physician might be guilty of infringement of these regulations without any criminal intent that the subject of furnishing legal defense in these cases should be considered by the Society, and a special committee be appointed to take this matter up with the Counsel of the Society and report at the next regular meeting of the House of Delegates.

Report of Committee on Public Health and Medical Education.—Dr. JOSHUA M. VAN COTT of Brooklyn submitted this report, which recalled that in 1910 this Committee had urged the establishment of county diagnostic laboratories and it was then suggested that these laboratories be centralized in the State Department of Health. While the suggestions of this committee had not been literally realized, nevertheless they had been put into effect in both spirit and fact. As a great medical society they could not endorse too heartily what had been accomplished, and at the same time they pledged their enthusiastic support to all measures which would put all sections of the State on a parity in the point of securing to its citizens the benefits of modern medicine in its various departments. They could not, however, place the stamp of their approval upon any measure involving the expenditure of large sums of money collectible through the assessment of a commonwealth already overburdened with taxation. Compulsory Health Insurance fell within this category and should be opposed as disruptive of the best interests of the community. They were of the opinion that the best success for the State, in its effort to relieve individual sickness and raise the standard of individual health, would be found in the generous expenditure of moneys for the support and progressive development of our State Department of Health, the intensive education of the public in matters of personal hygiene and State sanitation in all of its ramifications, together with a program for the medical profession of the State, calculated not only to maintain a high standard of medical education, but also to avoid discouraging our best and brightest sons from entering the profession of medicine.

Report of the Special Committee on Public Health of the Greater City of New York.—Dr. E. ELIOT HARRIS submitted this report, which gave the results of an extensive investigation of the narcotic drug question. Questionnaires were sent to 2,464 superintendents of State, county, and municipal almshouses; 3,023 State, district, county, and municipal health officers; 4,568 superintendents of private hospitals and sanatoria. After analyzing the data derived from these sources the report showed that the illegitimate traffic nearly equals the legitimate, and smuggling from Canada, Mexico, and along the Atlantic and Pacific coasts was a source of illegitimate supply. Owing to the lack of proper records it had been impossible to do more than guess at the number of addicts in the United States, but taking all the collected facts into consideration the number is somewhere between 300,000 and 1,000,000. The reports showed that there was less drug addiction in the country than in the larger cities. The questionnaires on the narcotic drug situation showed the want of proper records and reliable statistics in a startling way, which the Federal and State governments should bestir themselves to remedy. In the Greater City of New York district, where compulsory registration of narcotic drug addicts has been in force since July, 1919, there have been registered about 9,000 addicts, which is believed to be considerably less than the whole number resident in that district. Of the number of addicts registered, 7,464, 26 per cent had to do with transportation, as chauffeurs, motormen, and drivers, and altogether representing 175 occupations, passed through the Emergency Clinc of the New York City Health Department. In conclusion, the report made the following recommendations: 1. That the ambulatory treatment of drug addiction, as far as it relates to prescribing and dispensing of narcotic drugs to addicts for self-administration at their convenience, be prohibited by law. 2. That heroin be eliminated from all medicinal preparations, and that it should not be administered, prescribed or dispensed, and that the importation, manufacture and sale of heroin should be prohibited in the United States. 3. That the bill introduced by Senator France of Maryland to provide aid from the United States in prevention and control of drug addiction and the care and treatment of drug addicts be approved, and that Senator France, chairman of the Committee on Public Health, be so notified. 4. That the Bureau of Public Health service of the Treasury Department be respectfully requested to continue the compilation of State laws and regulations relating to habit-forming drugs and bring them up to date.

Report of Special Committee on Drug Addiction.—Dr. W. MEDDAUGH DUNNING submitted this report, the findings of which corresponded with those presented by Dr. Harris. The report stated that during the past year there had been an adaptation and coordination between the State and Federal laws. Further experience would increase this harmony as the provisions of the law grew more familiar, and there would be less misinterpretation and friction. The committee recommended the discussion of ways and means to avoid the present delay in the receipt of the necessary drugs for office, clinic, and hospital. In view of the large amount of opium used in the United States, as compared with other countries, this committee recommended stricter government supervision. 5. With reference to legislation concerning veronal, trional, sulphonal and other coal-tar products, the committee deprecated legislation until further investigation gave us more definite facts. At present it would seem that the percentage was small. 6. In view of the lack of uniformity of the various State laws, this committee cordially supported the recommendation of Dr. Harris that there be a collection and classification of all State laws, court decisions, regulations, and methods of administering laws on Narcotic Drug Control, and that this be done either by the Government Health Service or by the Internal Revenue Bureau for the benefit of officials and others in the several States.

Report of the Special Committee to Consider Economic Methods of Caring for Public Health.—Dr. E. PARK LEWIS of Buffalo submitted this report, in which it was

stated that it would be impossible for any committee to make judicious recommendations by which the obvious needs in this particular could be carried into effect without a much fuller knowledge of the exact conditions obtaining throughout the State than was now available. A knowledge of the number of hospitals and the degree of efficiency that they had attained and their approximation to a standardized ideal was of first importance, as it was to the staffs of existing hospitals that we should look for the establishment of diagnostic community clinics. The extent of preventable and of curable disease should be known and many other facts should be secured and correlated in order that proper deductions might be drawn before any plan could be proposed for the establishment of proper relation between the medical profession and the public. The more imperative needs were not for the very poor, and it is not desirable that efforts be made for increasing the number of charitable institutions, but a genuine need existed for the establishment of pay clinics in which group diagnoses could be secured at fees commensurate with the means of the patient and through which the physician in charge of any case would be enabled to secure correct treatment without danger of losing control of his patient. In order that the responsibility of the State toward its people in providing such facilities as will enable every practising physician to secure such necessary diagnostic aids as would enable him to give to his work its highest efficiency, it was recommended that a committee be appointed to prepare a suitable memorial to present to the next Legislature requesting the appointment of a committee by the Legislature empowered to investigate the needs outlined and to devise means through which they might be carried into effect.

Report of the Counsel.—Mr. JAMES TAYLOR LEWIS submitted a report showing that during the past year 27 cases had been disposed of, and juries had found verdicts against the defendants in two cases; one of the cases involved the claim of failure of diagnosis and improper treatment of fracture of the thigh, and the other the leaving of a broken needle in the abdominal wall of a patient after operation. A notice of appeal to the Appellate Division had been served in the former case, and a motion for a new trial had been made but not yet heard in the other. He had no doubt as to the successful final termination of both of these cases. There were 39 new actions brought during the year, being about the same as for the past four years. Of the number of cases tried in court during the last year, five had been those in which it was claimed some material had been left behind after an operation. This was a very much larger proportion of these cases than usually occurred. Attention was also called to the fact that this class of litigation was getting into the hands of a different class of lawyers. While formerly malpractice cases were confined in a considerable degree to lawyers of small practice and of not particularly high standing, this condition seemed to be changing. After citing the new cases for 1919, Mr. Lewis said that this year having completed twenty years of active service on behalf of physicians and surgeons of this State in the defense of malpractice cases it might not be out of place to furnish the members of the Society with some of the results accomplished during that time. The first case which he defended while he was attorney for the State and County Medical Associations was tried on Dec. 14 and 15, 1899. Since that time he had had come before him 811 malpractice cases, involving practically every known fracture of the human body, and the leaving behind of surgical instruments and varieties of dressings. During this time claims against defendants had aggregated upward of $12,000,000. There had been actually paid to plaintiffs less than $6,000. Finally, the year 1919 had been most satisfactory; the cases were growing slightly less in number, but more and more difficult to successfully defend, requiring of the Counsel continuing examination of the law, and the study of medicine, surgery, and anatomy especially.

Report of Committee on Medical Research.—Dr. FREDERIC E. SONDERN submitted this report which stated that during the current session of the Legislature up to the present, but one bill had been introduced which tended to restrict animal experimentation by excluding dogs for this purpose. This was Senator Boylan's measure entitled "An act to amend the penal law in relation to experiments on living dogs." A public hearing was held in Albany on March 10, at which this committee and the profession were ably represented. The bill was still in committee at this writing.

Report of Committee on Prize Essays.—Dr. EDWARD D. FISHER submitted this report in which he stated that the committee had received three essays, which was somewhat more encouraging than during previous years, though they were still disappointed that so few entered the competition. The money was, of course, not the real recompense, but the fact that the man winning the prize could pride himself on being a man of ability. There were two prizes, the Merritt H. Cash and the Lucien Howe. Two of the essays submitted were for the first prize and one for the second. The Merritt H. Cash prize was awarded to Dr. H. B. Sheffield of New York for his essay entitled "The Present Status of Poliomyelitis."

These reports were accepted and recommendations referred to the reference committees.

Report of Committee to Consider Method of Determining Partial Loss of Vision.—Dr. ARTHUR J. BEDELL of Albany submitted this report drawn up by a committee appointed to consider the question of partial loss of vision. It called attention to the urgent need of a uniform and authoritative method for determining loss of vision or partial loss of sight in workingmen. The report recommended a proper working basis for the computation of partial loss of sight three essentials: 1. Central visual acuity; (2) field vision; (3) stereoscopic vision.

Resolution Raises Dues.—Dr. WENDELL C. PHILLIPS introduced a resolution calling attention to the fact that the Society was facing a period when it might have extreme difficulty in meeting its bills, and particularly as they had adopted the recommendation to employ an executive secretary and providing for a special tax of one dollar per year per capita on the membership of the society. This resolution, he said, was presented because it would take two years before resolutions making a change in the constitution providing for an increase in dues would bring an increased amount of money into the treasury. This resolution was amended by a motion to make the special assessment $2 instead of $1. The amended resolution was adopted by the House.

Election of Officers.—*President*, Dr. J. Richard Kevin of Brooklyn; *First Vice-President*, Dr. W. Meddaugh Dunning, New York City; *Second Vice-President*, Dr. Wesley T. Mulligan, Rochester; *Third Vice-President*, Dr. W. H. Purdy, Westchester; *Secretary*, Dr. Edward Livingston Hunt, New York; *Assistant Secretary*, Dr. Charles Gordon Heyd; *Treasurer*, Dr. Harlow Brooks, New York; *Assistant Treasurer*, Dr. Seth M. Milliken, New York; *Chairman of Committee on Scientific Work*, Dr. Samuel Lloyd, New York; *Chairman of Committee on Public Health*, Dr. Joshua M. Van Cott, Brooklyn; *Chairman of Committee on Legislation*, Dr. James F. Rooney of Albany; *Chairman of Committee on Medical Economics*, Dr. Henry Lyle Winters, Cornwall; *Chairman of Committee on Medical Research*, Dr. Frederic M. Sondern, New York; *Delegates to the American Medical Association*, Dr. Eliot Harris, New York; Dr. Eden V. Delphey, New York; Dr. Arthur J. Bedell of Albany; Dr. Edward Livingston Hunt of New York; Dr. Dwight J. Murray of Syracuse; Dr. Richard J. Kevin, Brooklyn; Dr. Frederic M. Sondern, New York; Alternates, Dr. Frederic M. Sondern of New York, Dr. James Flemming of Brooklyn, Dr. George W. Kosmak, New York; Dr. Nathan B. Van Etten of New York; Dr. Nelson O. Brook, Dr. Albert T. Lytle of Buffalo.

Speaker and Vice-Speaker.—Resolutions providing for changes in the by-laws providing for the election and a speaker and vice-speaker were adopted by the House, following which Dr. E. Eliot Harris was elected speaker and Dr. Dwight H. Murray, vice-speaker.

Resolutions on Compulsory Health Insurance.—Resolutions were passed protesting against the insinuations contained in the report of the New York League of Women Voters which implied that their position with reference to compulsory health insurance was influenced at the instance of up-State or any other league of business men, and stating that their position was

uncompromisingly opposed to compulsory health insurance because it was destructive of the best interests of the medical profession and inimical to the public welfare. Resolutions were also adopted instructing the delegates to the American Medical Association to introduce resolutions opposing compulsory health insurance and to do all in their power to support such resolutions.

GENERAL MEETING.

Tuesday Evening, March 23.

THE PRESIDENT, DR. GRANT C. MADILL OF OGDENSBURG, IN THE CHAIR.

Address of Welcome by the Chairman of the Committee on Arrangements.—Dr. CHARLES H. PECK made a brief address of welcome in behalf of the medical profession of Greater New York and the official medical body of the County of New York, in which he said that they felt honored to have the annual meeting of the Medical Society of the State of New York in this city. Many things had happened since they met in New York in 1914. Many of the members of the society had had thrilling experiences in the great war and all who had gone had not returned. The influences of the war still continued to be a vital factor in our lives. He hoped the arrangements for the entertainment of the members and their guests would afford them profit mingled with pleasure. He trusted that they would find New York not a half bad place even if some of the amusements were missing that they had before the war.

President's Address.—Dr. GRANT C. MADILL delivered this address in which he said that as the echoes of war died away, new questions and complex problems arose, and although sixteen months had elapsed since firing had ceased, the world was still laboring to bring order out of social chaos. The problems to be solved involved social, industrial, economic, and governmental conditions. The causes of this social unrest had been studied from every angle without, as yet, definite results. During the period of the war man had reverted to primitive instincts and the individual willingly sacrificed wealth and life itself for the benefit of the herd—society. We were forced to realize that, with all the centuries of civilization, man still remained a biological element and regressed to the methods of the savage, when the welfare of the State demanded it. When the necessity for herding was ended the individual became conscious of self again, and soon began to drift to pre-war selfish initiative. We were now having class struggles with greater intensity than ever existed before the war. As the result of various efforts to bring about order and contentment from the maze of social unrest, we had leaders among the different groups, who hoped by revolutionary means, to bring about what should come by a process of evolution, which was the natural, conservative, and dependable means of biological progress. To those with an abnormal amount of sympathy and sentiment the law of struggle for existence and "survival of the fittest" appeared crude and barbarous. To the American-born there was, however, an added zest to life in the challenge expressed in struggle for existence and the Government stood as umpire in securing fair play, protecting the weak, and preventing infringement on the rights of others. They as physicians were concerned in the numerous social problems in which the State was interested, and in addition they had their own special problems, depending upon the close relation of medical advances with general industrial and social questions. They were passing through an era when many traditions, beliefs, and customs were being put in the scrap heap or the melting pot and the practice of medicine could not stand still. Dr. Madill then referred to the stand which the society had taken on Compulsory Health Insurance and urged that physicians should not become self-centered in their professional work and forget their duties as citizens. Though the House of Delegates had opposed Compulsory Health Insurance they had passed resolutions asking for an unbiased investigation to determine the amount and character of illness in its relation to the commonwealth, and urging that if additional legislation was to be enacted, it should provide for the development of existing agencies for preventive medicine. This meant that the Medical Society of the State of New York preferred the gradual evolution of state medicine to any form of health insurance. The progress of State and Federal medicine had been so gradual that the public and even physicians were scarcely aware of the vast amount of medical practice that was being done by physicians in this service. To realize this one need only recall the large number of institutions for the care of the insane and hospitals for the care of the tuberculous, and the many activities of the State Department of Health. The State was furnishing funds to carry on these numerous activities, and was showing deep interest in the health and welfare of its citizens. In addition to the State Board of Health there was the United States Public Health Service. For the performance of certain health functions there were other Federal departments. In the conduct of this work Congress had appropriated $8,338,470 for the fiscal year ending June 20, 1920, to the Public Health Service. Of this amount $3,000,000 was to be used for public health work. There was need, however, of greater coordination of Federal, State, and local health activities, and undoubtedly this would not result until there was one administrative head with a cabinet officer in charge of the Department of Health. That state medicine would eventually come, required no great imagination to predict. It would probably come gradually by a process of evolution, and could be developed in such a manner that the medical profession would not be deprived of its original prerogatives. It must be so adjusted that the spirit of individualism and initiative in medicine were not clouded. Remuneration for services must be on a scale sufficiently large to enable the physician to live well, educate his children, and enable him to retire at sixty-five to live on a pension. A fixed salary for a medical man would be a blessing, particularly to those practising medicine with a profound interest in the scientific aspect of medicine. The medical man was notoriously a poor business man and an annual budget would in many ways be a relief. The one great objection to any system of state medicine was the danger of the Department of Health becoming the victim of political patronage. After speaking of the need of more physicians in rural districts, Dr. Madill said it would be necessary for hospitals to expand in order to meet the demand for institutional care, and it might be that the State would be called upon to aid financially in enlarging hospitals already existing and in the construction of new buildings. When the survey of the State, to determine the amount of illness in its economical relation to the commonwealth, was completed, a basis would be established upon which an estimate of the cost to the State could be computed. The cost would undoubtedly be great, but the conservation of health and the prolongation of life was the most important function of the State, and the benefit economically considered amounted to millions. To successfully establish and put in action a system of State medicine would require deep study economically, sociologically, and from the point of view of the physician. Dr. Madill declared that to-day medicine was not attracting students in sufficient numbers to supply the demands of private practice, hospitals, State and national institutions, the army, navy, and public health service. It was his belief that the cost of obtaining a medical education, together with the comparatively small remuneration of the physician, was responsible for the small number of men entering the profession. The standard of medical education should not be lowered. Either the State or the universities must make provision for the education of students with a desire for and mental qualifications adapted to the study of scientific medicine. While he felt certain that income was by no means the determining factor which induced a young man to study medicine, it was essential that the reward be sufficient to maintain a dignified position in society. The practice of medicine in the future would undoubtedly be carried on by what was known as group clinics, either diagnostic alone, or diagnostic and remedial. Group practice would be of inestimable value to all classes, rich and poor, alike. This system was not an experiment as we had several conspicuous

examples of its success throughout the country. The State had already made a step toward this type of practice by employing specialists and diagnostic experts in contagious diseases, tuberculosis, muscle and joint deformities following infantile paralysis, and other special diseases. Undoubtedly as State medicine developed and health centers were established a staff of specialists would be employed to provide group study for those unable to afford the cost of examination by private groups.

Annual Oration.—Dr. JOHN H. FINLEY, LL.D., L.H. D., Commissioner of Education and President of the University of the State of New York, delivered this address. He said that if he had the part of determining what books of the Bible should be canonical, he would vote for Ecclesiasticus or the wisdom of the Son of Sirach. He would at least follow St. Augustine in making frequent use of it, and he would follow St. Jerome that it should be read for the instruction of the people, even if it was not followed in theological dogma. Not only in things spiritual were these writings remarkable, but they had some brief and sententious passages on disease. Nothing better had been written than this essay of the Son of Sirach which was written in Egypt 132 B. C. It was the sort of an essay that Abraham Jacobi or William Osler might have composed. Most of our modern writings were not apocryphal. It was only such men as these who compared with the early Greek and Hebrew writers who were able to write better than the men of to-day. He felt that he must also include Grover Cleveland, who addressed this Society in 1906 and closed his oration with the clause "for you have to do with the temples of the Holy Ghost." He said he could not forbear recalling these men who were great doctors, great philosophers, and noble friends. Dr. Jacobi had been called the great "friend of truth," and a "sad friend of truth." As he saw the box bearing the name of Dr. Jacobi being brought to New York he thought "We bring nothing into this world and it is certain we take nothing out of it," but how much Dr. Jacobi had left for all he brought so little into the world, and he had taken with him only his burial clothes and the covering the trees had provided. The great men of the world, the Newtons and Bacons, had been givers and not grabbers.

Dr. Finley quoted freely from the Scriptures and from an ancient oration, to show the esteem in which the physician had been held in ancient times, one quotation ending "All things are not provided for all men, neither do all souls need all things. In a multitude of 'eats' there shall be disease, and surfeiting shall go into colic, but he that taketh heed shall prolong his life." Dr. Finley declared that he was not so much interested in prolonging life as in making life full and happy. It was not too much to say that he that taketh heed should prolong his life. A most comprehensive program for the application of this advice was found in the conception of the law of the State of New York which looked to the formation of health habits for every child, not only in eating, but in drinking and caring for the body as the temple of the Holy Ghost. The law was construed as covering an individual health examination and personal health instruction concerning the important facts of hygiene and physical exercise as health habits. The exercise consisted in gymnastics, marching, and supervised play. This did not take the place of the work of the medical inspector or the school nurse. The State Department of Education cooperated with the State Department of Health in seeing that a child had frequent examinations and especially if he had serious organic weakness. There were outside of the City of New York 1,276,000 children, or 75.1 of all the children in the schools outside the city of New York who were examined, and 986,000 defects were found, of which 286,000 were repaired. That percentage was not as large as they wished. They were now working on a revision of the syllabus of State Health work by Dr. Biggs and members of this Society, the sole object of which was to transform health maxims and rules into health habits. This program Dr. Finley said he would not give in its entirety as it was in preparation only. (See report House of Delegates). was a lack of teachers to carry it out. A law without One great difficulty confronting them was that there teachers, physicians, and health inspectors was impotent. They did not expect to do as he had heard was done in one instance where a medical inspector examined 80 children in 60 minutes and used the same tongue depressor for all. Their need was for real health teachers who would work in cooperation with the Board of Education and the Health Department and this would give, not health insurance which they did not want, but health assurance which they wanted and which this Society could support.

Coming to another part of his quotation "Honor a physician according to thy need, for verily the Lord hath created him," Dr. Finley said "Honor the physician according to the State's need and according to the child's need in the State." He had always envied the physician who had the satisfaction of knowing that he had prolonged life, while those who worked with ideas never knew whether they had harmed or helped. He told the story of the doctor in the Bonnie Brier Bush by Ian MacLaren to illustrate the unselfishness of the true physician and expressed the opinion that the Medical Society of the State of New York would be doing a worthy deed if it could make physicians as unselfish as St. George or as Ian MacLaren's doctor. He quoted again from his ancient oration "Acquaint thyself of the physician before thou have have need of him," and recommended that advice. He felt that annual registration would do much to prevent impostures and to protect the people in the selection of a physician. The man who rebelled against it was not a true benefactor. Dr. Finley said he signed the licenses to permit physicians to practise in this State. It was a great and solemn responsibility as well as a high honor to open the door to all who entered, and when he bestowed a license on a young physician he prayed in the words of Grover Cleveland "tread lightly for you have to do with the temples of the Holy Ghost," and he administered in thought to all the ancient Hippocratic oath. This Dr. Finley quoted in closing.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 24, 1920.

DR. LILIAN K. P. FARRAR IN THE CHAIR.

Meningitis in an Infant Six Days Old.—Dr. ELISE L'ESPERANCE reported this case. She stated that labor was normal, the child apparently normal at birth. On the third day the child's temperature was 100.2° Fahr.; on the fourth day the temperature dropped to normal. On the fifth day the child had convulsions, and died on the sixth day. Autopsy showed a well-developed child. The caput was normal, fontanel slightly bulging. The meninges were covered with purulent, yellowish exudate, more marked along the sinus and dipping into the sulci. The rest of the autopsy was entirely negative, with the exception of a punctate hemorrhage in the lungs which were partly atelectatic. Examination of a smear of the exudate from the meninges showed the pneumococcus. No spinal fluid was withdrawn during life. This case was reported because few cases of meningitis in the new born had been reported. She felt that this was not because the condition was so rare, but because the diagnosis was not made, or they were taken for cases of meningeal hemorrhage. The case was also interesting from the standpoint of the method of infection. In many of the reported cases the infection was believed to have occurred through the navel, though some believed the infection gained entrance through the nose or mouth. The fact that many cases showed the colon bacillus made that seem quite possible. In this case the cord was absolutely normal. The child had had a slight nasal discharge, but nothing more than one frequently saw following delivery. She felt that in this case infection had occurred through the nose or mouth. In the reported cases the organisms most frequently found in their order of frequency were the colon bacillus, the streptococcus, pneumococcus, and the meningococcus.

Ectopic Pregnancy.—Dr. L'ESPERANCE reported this case from the obstetrical service of the Harlem Hospital. The patient gave a history of having been taken with cramp-like pains in the abdomen three days before admission to the hospital. These pains became

more severe, and were accompanied by a slight vaginal discharge. At the time of her admission to the hospital the diagnosis of ectopic pregnancy was made, and the patient ordered prepared for immediate operation. Before the preparation was complete she died. At autopsy the abdomen was found to be filled with blood-stained fluid, and a most perfect specimen of a ruptured ectopic gestation was found. This specimen was presented. The patient had menstruated last on December 14, 1919, which made the gestation one about two months' duration. There was an extreme decidual reaction in the uterus. This reaction occurred in many ectopic pregnancies, and in some instances a cast of the uterus had been discharged through the vagina. This decidual reaction was a pathognomonic sign of ectopic pregnancy.

Dr. BAILEY spoke of the first case in which the infant died of meningitis six days after birth. He said that likely Dr. L'Esperance did not recall that she had had a similar case at the Manhattan Maternity Hospital, in which there was a normal delivery in an induced labor in a woman with a contracted pelvis. The labor was induced with bags, and after the bags were removed the uterus contracted for a considerable period. At birth the baby was apparently normal. On the second day it had a temperature of from 101° to 103° Fahr., which rose to 105° on the morning of the fifth day, and the baby died. This baby, on the first day, had the typical meningitis cry. Whether the condition was the result of pressure in the contracted pelvis could not be determined. At autopsy an exudate was found over the parietal region. There was no fracture. Dr. Bailey said he had had recently another case with typical meningeal symptoms following a forceps delivery. Immediately after delivery there was marked swelling beneath the periosteum over the parietal bone and fracture. This baby also had a typical meningitis cry, and the lungs were atelectatic. On the fourth day the child showed marked retraction of the neck. Spinal puncture showed blood in the spinal canal. At autopsy there was no meningitis, but hemorrhage outside the meninges and rupture of the tentorium cerebelli.

Dr. S. W. BANDLER said the specimen was a beautiful one, and the decidual rection marked and exceedingly interesting. He asked with reference to the frequency of discharge of a decidual cast.

Dr. L'ESPERANCE replied that at Cornell they had had several instances in which the diagnosis had been made by the uterine casts being thrown off. She cited two instances in which decidual casts were thrown off in ectopic gestations of three months' duration.

Dr. BANDLER said this throwing off of a cast of the uterus was occasionally an important and interesting point in connection with the diagnosis of ectopic pregnancy, more particularly if it were found that these casts were thrown off more frequently than are thought. He thought one must feel that they were thrown off frequently and that the patient went on to recovery without our knowing positively that she had had an ectopic pregnancy. Many tubal pregnancies ended in a complete tubal abortion, in the early stages, and no further annoying symptoms developed.

Dr. FARRAR said that in going over the history of a large number of cases of ectopic gestation with another object in view she had been interested in observing how often the history showed that a body was thrown off from the uterus which the patient thought was due to a miscarriage, so that it became quite difficult to tell from the history whether a cast of the uterus had been thrown off or not. There were many cases in which the reports were made in the hospitals which showed that casts of the uterus had been thrown off, and in three or four instances there were complete sacs thrown off during the time the patient was in the hospital.

Dr. KOSMAK said it was rarely that we did not have irregular bleeding as evidence of this condition, yet in his experience it was very often absent, and the first evidence of an ectopic pregnancy was the rupture of the sac. They had had a case coming into the hospital within the last two weeks in which the only evidence of ectopic gestation was the symptoms of internal abdominal hemorrhage and a history of having skipped two or three periods, there being no evidence of uterine bleeding whatever. Inspection of the cervix showed nothing. This woman had had a tubal abortion with rupture of the artery running along the tube, and the fetus had escaped through the fimbriated end of the tube into the abdomen, as shown by the tear in the fimbriated end of the tube, together with the ruptured blood vessel. He had seen a number of these cases with no external hemorrhage, so he thought the symptoms of irregular bleeding should not be relied upon as an absolute factor in the diagnosis of these cases. In the case just referred to the uterus was very small and the woman had had no lochial discharge, so there was nothing in the way of a decidual reaction to manifest itself.

Dr. THOMPSON T. SWEENY said the question of a decidual reaction depended upon the time that had elapsed after the rupture of the fetal sac before the case was seen. He related a case in which there was a double pyosalpinx and also a tubal pregnancy in which a cast was thrown off. At operation a ruptured tube surrounded by hematoma were found. He thought the reason Dr. Kosmak did not see decidual casts was because he saw cases at the time of the initial hemorrhage and operated at once. He thought that if these cases were not operated on at once bleeding from the uterus would follow and one might see casts thrown off.

The Influence of the Male Parent on the Production of Human Twins.—CHARLES B. DAVENPORT, Ph.D., read this paper. (See page 509.)

Dr. CHARLES R. STOCKARD continued the discussion of the subject, illustrating his talk with lantern slides. He said they had long recognized that all qualities and conditions might be inherited, but they had not known so much about the two types of twins, and that double egg twins were about one-third as frequently inherited as single egg twins. He agreed entirely with what Dr. Davenport said with reference to the double chorion. There were also other cases, not so common, in which there were twins in separate embryos which were at first surrounded by separate sacs which later fused and the embryos might be either male or female. That happened in the South American armadillo that always had twins instead of quadruplets, but not always of the same sex. The problem of ovulation had been worked out by experiments with dogs, and it had been definitely shown that types of ovulation were inherited. In some instances several ova were found in one follicle, and when this was the case there were two or three times as many offspring as when there was only one ovum in a follicle. In some animals, like the guinea pig, ovulation occurred in both ovaries at once, and if one ovary was removed the other took up its functions and as many ova were produced as though both ovaries were functioning. There were never more corpora lutea than ova, and if there appeared to be more it was due to certain lethal factors that brought about the destruction of the ovum. Many ova were arrested in development on account of a disadvantageous position which they held. A whole embryo might be absorbed. If double ovulation was inherited that was a quality that could be transmitted by the male. Identical twins were produced when embryos were equal in size and normal in structure. As soon as there was a difference in size the smaller one would be deformed, and in such instances, the eye being the most sensitive structure, was the first to be affected. Dr. Stockard showed slides illustrating his experiments on fish whereby he had been able to produce double monsters. The factor which was responsible for this was the slowing of development in an early stage of embryonic growth. The degree of doubleness was determined by the angle the axis of the second embryo made with the first. Dr. Davenport had brought out that there might be inheritance through the father, and this slowing effect on the early development might also occur through the father. They found that when oxidation was low it had an effect on the spermatozoa which resulted in a slowing of the development of the fertilized ova. In man, because of his abnormal ways of living, this slowing effect was more likely to occur than in animals, so that one might get these defects through the male.

Dr. THOMPSON T. SWEENY said it was known that certain hybrids, such as mules, would not fecundate the mare. Just as the earless ram, they were sterile. Was this due to abnormal development of the testes or to lethal factors?

Dr. BANDLER asked if he understood correctly that all twins from one ovum were of the same sex.

Dr. DAVENPORT said yes they were.

Dr. BANDLER said that was his opinion, based on all records and reports, and on the basis of the chromosomes one saw double ectopics, and the double ectopics would show two eggs and two Graafian folicles. He believed that for every nidation that took place two or three ova died without becoming implanted. A woman might not be more than one or two days over a period, and the fertilized ovum might be in the uterus and menstrual stimulation might force it out. He believed that fecundation occurred thousands of times without nidation. In the treatment of sterilities it was well to have this in mind. One might feel certain that the spermatozoa met with the ova, but it was most important also to see that nidation took place. It was perfectly possible to have two ova fertilized, one of which would nest and the other not. Or one might remain two or three months and the other go on to term. He wondered whether this occurred as often as one might think. The earlier this occurred the less would be the evidence external to the membranes. The occasional passing, in the post-factum period, of a "bloody hard mass" after inspection immediately after the third stage had shown membranes and placenta to be intact, might be explained as above.

Dr. DAVENPORT said that in the case of the hybrid mule it was known that the spermatozoa did not develop properly. They had been trying until recently to make sure that the earless ram was sterile. They expected to kill the animal and make observations on the testes, but had not done it as yet. In regard to the failure of nidation, they did have the phenomena of the blighted fetus and instances in which the fetus developed for three or four months and then its growth was arrested, and he suspected that it happened oftener than we knew of.

An Analysis of One Hundred Cases of Placenta Praevia.—Dr. LANGROCK and Dr. GEORGE L. BRODHEAD presented this paper.

Therapeutic Hints.

Dried-Milk Feeding.—Vynne Borland, in discussing a scale for feeding infants on dried milk, holds that such a scale should fulfil the following conditions: (1) It must be practicable. (2) It must be easily understood by doctors, nurses, mothers, or any person having charge of the baby. (3) The calculated amount of feed must produce a satisfactory gain in weight per week. (4) The stools must remain normal. An investigation was carried out primarily on 69 babies of ages ranging from 3 weeks to 8½ months, and weights ranging from 6 lb. 7½ oz. to 21 lb. 1¾ oz. The smallest feed which produced a satisfactory gain, the baby otherwise being in good health, was chosen from the clinic cards and noted. In this way 188 feeds at various weights were obtained. These were arranged in successive increasing weights and an endeavor made to produce a simple formula that could be used for guidance. After trying several means of obtaining a suitable formula it was found that by adding the number 9 to the weight if below 7 lb. and the number 10 to the weight from 7 to 16 lb. inclusive, the required number of level teaspoonfuls of dried milk to be given in 24 hours was obtained. From 17 lb. upwards when the child is having four feeds in 24 hours the second figure of the number of pounds' weight is taken as one feed. For example, if the weight is 17 lb. then four feeds are given each containing seven level teaspoonfuls of dried milk. Attention is directed to the fact that all the various "full-cream dried milks" are reconstituted by a dilution of 1 in 8—*i.e.* one level teaspoonful to an ounce of water. The formula is thus stated:

Below 7 lb. add 9 to weight = up to 16 level teaspoons in 24 hours.
From 7 to 16 lb. add 10 to weight = 17 to 26 level teaspoons in 24 hours.
From 17 lb. upwards take second figure as one feed = 28 teaspoons upwards.

—*The Lancet.*

Internal Medication in Gonorrhea.—Arthur H. Crosbie of Boston, in a discussion of the treatment of gonorrhea in the male, says, with reference to internal medication, that after trying out many things he has come down to two simple old remedies.

He uses sandalwood oil capsules, three times a day after meals, and before meals a teaspoonful of a mixture of

℞ Tincture hyoscyamus..... ℥viss
Potassium citrate ..... ℥v
Water up to ..... ℥iv

The hyoscyamus, he says, is excellent to prevent chordee. If chordee is present he gives a fourth of a teaspoonful at bedtime. The potassium citrate helps to render the urine bland. He considers water under internal medication, because he feels that a large amount of water is more important than any other thing. Enough water should be taken so that the urine almost entirely loses its color. The patient should be instructed to drink at least a glass of water every hour during the day. This will render the urine bland and keep the discharge frequently washed out.—*Boston Medical and Surgical Journal.*

INFECTION OF INTESTINAL ORIGIN COMPLICATING PREGNANCY, LABOR, AND THE PUERPERAL STATE.*

BY EDWARD P. DAVIS, A.M., M.D., F.A.C.S.,

PHILADELPHIA, PA.

PROFESSOR OF OBSTETRICS IN THE JEFFERSON MEDICAL COLLEGE.

IN our efforts to promote the welfare of the patient through what is termed the hygiene of pregnancy, nothing is more important than the care given to the functions of the intestinal tract, and this is distinctly recognized as among the necessary elements in the management of successful pregnancy. While we are familiar with isolated conditions complicating parturition and having their origin in intestinal infection, we do not always group these together as one pathological entity. Possibly there may be something gained if we make a distinct group of these complications, contrasting them with puerperal septic infection of uterine origin and its manifold phenomena.

It is a matter of familiar knowledge that the intestine in the human being swarms with bacteria, notably the colon bacillus. The mechanical conditions prevailing in the abdomen as pregnancy advances are such that interference with the peristalsis of the bowel and the accumulation of fecal matter during pregnancy are inevitable. In addition to this, congestion of the abdominal viscera must be present to some degree during pregnancy in the majority of patients, and a combination of these two conditions furnishes a state of affairs exceedingly favorable for the development of infection of intestinal origin.

This may manifest itself most frequently in appendicitis, cholecystitis, infection of the pelvis of one or both kidneys, infection of the lymphatics of the intestine and peritoneum, or infection of the blood stream. With these we are more or less familiar and the first question which naturally presents itself is, what can be done during pregnancy to render such infection as infrequent as possible?

While some patients pass through pregnancy without the use of purgatives and laxatives this is not true of the majority. What is desired is to render the fecal mass in the bowels soft and unirritating and to promote peristalsis and to keep the bowel in a tonic condition. In the use of drugs care must be taken that the ganglia in the uterine muscle are not stimulated to contraction by drugs which stimulate peristalsis of the bowel, for excessive uterine peristalsis will cause abortion. That there is danger in the prolonged retention of hard feces in the intestine of the pregnant women was demonstrated to the writer when at autopsy upon a woman dying in labor hardened fecal masses were found in the intestine which were about to rupture the bowel. The mechanical action of the uterus in labor had pressed them against the wall of the intestine to the point of imminent rupture.

Recently, in abdominal surgery, there has arisen a decided opinion that active purgation just before abdominal operations is a mistake. It has been observed that, when fecal masses are softened and the bowel is aroused to active peristalsis, there is more disturbance immediately after operation, and that in the event of the necessity arising for operating upon the bowel itself the chances of infection are very much increased. At present we prefer to empty the patient's bowel thoroughly several days before operation. Or if this opportunity is lacking we content ourselves by cleansing the lower bowel by gentle irrigation and avoid the depressing and irritating effects of active purgation. That the use of irritant drugs may result fatally is a fact not unfamiliar to coroner's physicians and was strikingly illustrated in the experience of the writer when a young woman died shortly after labor from peritonitis. It was supposed that she had lost her life through puerperal septic infection, but at autopsy the pelvic organs were normal while the lymphatics of the intestines and peritoneum were in a state of acute engorgement and infection. This was found to be due to the presence of the colon bacillus, with others of less virulence, and when the history of the patient was obtained we learned that in the effort to destroy the life of the child and bring about a criminal premature labor the woman had taken large quantities of the most irritating purgatives.

The introduction of refined petroleum as a lubricant, the very common use of fruit and cereal foods during pregnancy all tend to relieve the patient of the danger of irritation of the bowel. What, however, is especially needed to promote intestinal peristalsis in pregnancy is exercise by walking. In modern life this is becoming more and more infrequent. The appliances which women wear upon their feet are designed to prevent walking, the common use of motor cars and in cities crowded streets render walking one of the most infrequent forms of exercise. Where this cannot be procured calisthenic exercises during pregnancy are of considerable value and should these be impossible massage by skilful hands may often be employed to great advantage. Exercise, cold bathing followed by gentle rubbing, the plentiful use of fruit, water,

*Read at the joint meeting of the New York and Philadelphia Obstetrical Societies, March 9, 1920.

and cereal foods, and regular and systematic attention to the matter will enable many patients to pass through pregnancy without the use of purgatives. If laxatives are necessary refined petroleum as a lubricant, with compound licorice powder, is often successful. In the presence of toxemia drugs which act vigorously upon the eliminative organs must be used, but without this indication purgation during pregnancy should be avoided.

Appendicitis is a matter of such common observation that I need not detain you to discuss it in this connection at any length. Its diagnosis in pregnancy is often interesting because the obstetrician must distinguish between appendicitis, tubal gestation on the right side, and threatened abortion of an intrauterine ovum. It is, I think, common experience that so soon as the diagnosis of infection of the appendix is made during pregnancy the appendix should be removed. In the experience of the writer abortion is rare and the earlier in pregnancy this is done the less difficult is the operation and the better is the chance for uncomplicated recovery. The median incision is preferable, for one can never be sure that the broad ligaments, tubes, or ovaries may not be to some extent involved in the infection. The leucocyte count is of considerable value in making the differential diagnosis.

In the presence of advanced pregnancy and appendical abscess, the uterus should first be emptied by section and closed, and then the abscess may be safely drained. In the puerperal period it is interesting to observe that appendicitis often develops from ten to fourteen days after childbirth. It must then be differentiated from puerperal septic infection with involvement of the right tube, and the fact that the patient may have a red, fluid, inodorous, lochial discharge may obscure the diagnosis. It must be remembered that infection of any sort complicating pregnancy or labor will produce a red, fluid, inodorous lochia if the infection be that of the blood stream. Those who have witnessed abortion or premature labor complicating influenza or pneumonia may have noticed this fact.

The differential diagnosis of colon bacillus infection complicating the puerperal state and attacking the appendix and intestinal lymphatics is made by first ruling out puerperal septic infection. The uterus will be found in a fair state of involution. There will be no mass or tumor in the pelvis, the patient will have made an apparent recovery from labor and will probably have been able to nurse her child. Lacerations in the generative tract will have healed and the general condition will be good. There will be, however, evidence of blood-stream infection, with rapidly increasing leucocytosis. Obscure tenderness will be elicited by deep pressure in the right lower abdomen.

The obscure and insidious nature of these cases may be illustrated by a multipara whose labor was induced for toxemia. Spontaneous labor was followed by a normal puerpal period, the patient nursing her child successfully. A week after returning to her home, high fever developed which fell on purgation. Obscure tenderness could be elicited on deep pressure in the right lower abdomen. There was a leucocytosis of 25,000. On section the appendix was seen to be gangrenous. The infection had extended to the right broad ligament and when grasped the Fallopian tube came away in the hand. With free drainage the patient recovered. Analysis of her history showed frequent attacks of indigestion with pain, extending over a number of years and requiring a carefully restricted diet and the use of drugs. Evidently a chronic catarrhal appendicitis had been present.

In a case operated upon a few days ago by the writer a young primipara had come to the 14th day of her puerperal period apparently well. Moderate fever and indefinite tenderness developed. On bimanual examination the pelvic organs were all normal. A thin, red, odorless lochial discharge appeared. The leucocytes at first were 8,000, but in 24 hours were 10,200. On section the abdomen contained reddish serum. The appendix was bright red and swollen and the peritoneum injected.

Obstetricians must go to the records of general surgery for their most valuable information concerning cholecystitis complicating pregnancy, parturition, and the puerperal state. There are abundant records of isolated cases in obstetric literature, but when the records of large surgical clinics tell us that in taking the histories of women operated upon for cholecystitis pregnancy is found to have been present in the greater number of these cases, usually in the first attack, we understand the position of the surgeon who recognizes pregnancy as a frequent cause or concomitant of cholecystitis. Strangely enough, many abdominal surgeons decline to drain the gall-bladder during pregnancy, cherishing the old belief that all operations are dangerous at this time. The writer is not prepared to say that all cases of cholecystitis of a mild grade complicating pregnancy should be subjected immediately to operation, but certainly this matter should receive careful attention at the hands of obstetricians.

That a condition of general toxemia in pregnancy may depend to a considerable extent upon a chronic infection of the gall-bladder was demonstrated to the writer in the case of a young primipara at term who was profoundly toxic. No adequate cause for her condition could be found by examining the urine. There was moderate leucocytosis, pain and tenderness could not be distinctly isolated in any one portion of the abdomen. Rest in bed, attention to diet and elimination did no good, and after observation for some time the conclusion was reached that several foci with abdominal infection must be present. Accordingly the patient was subjected to abdominal section. The uterus was first emptied and closed in the usual manner. The appendix was found in a state of chronic inflammation, partially filled with decomposed material and was removed. The gall-bladder was sutured to the abdominal wall and drained and a quantity of decomposed and offensive bile escaped. The patient made an uninterrupted recovery, her child surviving, and was discharged from the hospital in good condition. She had had little or no care during her pregnancy but the necessity for such extensive procedures must be rare in the majority of cases.

Colon bacillus infection of the pelvis of the kidney has been so thoroughly investigated by members of this Society that the subject is familiar.

The writer's experience may have differed somewhat from yours in that in a number of cases he has drained the pelvis of the right kidney through a lumbar incision after medicinal treatment had failed to improve the condition of the patient. The results have been gratifying in these cases and while it is seldom necessary to subject these patients to such an operation, we believe that there are cases where it is clearly indicated.

Infection of the lympathics of the intestine and peritoneum complicating the puerperal state has been described in the beginning of this paper as the result of irritating purgatives. It may also develop where no such distinct cause can be found. In the experience of the writer two cases stand out distinctly. One was a primipara who had suffered from chronic constipation during her adult life and who had passed through a spontaneous labor with very little laceration. The puerperal period was normal for ten days when moderate fever and indefinite abdominal tenderness developed. Purgation, ice bag, limited food did no good. Bimanual examination found no evidence of puerperal septic infection. Lacerations were healing kindly. On section the pelvic organs were normal, the appendix in chronic infection, and the lymphatics of the lower abdomen were reddened and engorged. There was beginning adhesion of intestinal coils and turbid serum in the abdominal cavity. The removal of the appendix, very thorough drainage, with Fowler's position and the Murphy drip proved successful. The second case was that of a Greek woman admitted to the hospital, in labor, who on the tenth day of the puerperal period showed more severe symptoms, of the same sort as those described in the former case. On section the condition was much more advanced, peritonitis had become established and the patient died. Autopsy failed to reveal evidence of puerperal septic infection.

Infection of the blood stream from various foci is much in evidence in the pathology of medicine in all its branches at the present time. If carried to excess the race bids fair to become toothless, tonsilless, minus the appendix, gall-bladder, diverticula, and whatever pernicious pockets may be discovered. There seems to be a sort of medical income tax developing, the purpose of which is to rob the owner of all foci and empty completely all pathological pockets. I am not aware that the obstetric pathology of the subject has been thoroughly worked out, but some clinical facts may be of interest. It is familiar experience in the management of the puerperal period that a free administration of salines with some patients is followed by a moderate fever. As a rule this subsides without injury. Is this fever caused by the absorption of dissolved fecal matter? Is it a nervous reflex through excessive peristalsis, or may there not be a mild infection which is overcome by the immunizing principles in the patient's blood? In non-puerperal cases the occurrence of peritonitis without injury or apparent contagion must be admitted. A young woman who was approaching a menstrual period and in whose case there could be no possibility of pregnancy, on an excessively hot summer's day took a cold tub bath. This was followed by the rapid development of peritonitis and death. At autopsy acute peritonitis was present and from the blood were isolated bacteria. In the absence of pregnancy, attempted abortion, vaginal manipulation, mechanical injury, irritant poison, to what source shall we ascribe the peritonitis? Was it caused by bacteria in the intestine which became greatly congested as the result of the cold bath; and did these bacteria enter the blood stream, or the lymphatics?

Obstetricians occasionally see cases of mammary abscess which develop in women who have never nursed a child and in whom there has been no manipulation of the breast and no wound or injury to the nipple. On examining a number of puerperal women before the child had nursed it was found that the fluid drawn from the breast by a sterile pump contained abundant bacteria. Did these bacteria gain access to the breast from the blood stream, or did they make their way from the skin along the lymphatics of the nipple? We cannot deny the possibility of infection of the blood stream through foci in the puerperal period. Cases of pyelitis are thus accounted for in some patients. In the observation of the writer a primipara after a normal labor under antiseptic precautions was taken with fever and rapid pulse from the eighth day of the puerperal period. As no cause could be found in the pelvis or abdomen, an examination of the patient was made, beginning with the skull. On coming to the mouth it was stated that a dentist had pronounced the patient in good condition just before labor. Permission was asked to palpate the teeth when at the root of one tooth tenderness was discovered. The patient then remembered that this was a tooth which had given trouble years before, but had become quiescent and was considered safe. The dentist was summoned in consultation and upon his incising the gum about a drachm of exceedingly fetid pus escaped and the disinfection of this focus caused the disappearance of the fever.

In presenting this subject before you no attempt has been made to give a lengthy review of the literature nor to advance theories. It is hoped that it may be useful to bring together this group of clinical phenomena and suggest a common cause for a number of conditions which cannot be rare among parturient women. It would be a great mistake to lessen in the eyes of the profession the importance of puerperal septic infection originating in the generative organs. But the differential diagnosis of complications affecting parturition must add to our knowledge and not detract from our accuracy or the interest of our study. May I urge again the importance of the hygiene of pregnancy and the care of the intestine and the avoidance of artificial methods so far as possible in maintaining the proper action of the bowels during pregnancy. Does it not seem rational to deal with infection of intestinal origin complicating parturition by surgical methods promptly and thoroughly so soon as the diagnosis can be established? While the experience of the writer has not been extensive, for these cases can not be exceedingly common, the results of surgical treatment have been in the main satisfactory.

The best part of a paper is usually the discussion which it brings forth. The Obstetrical Society of New York have entertained us to-day so liberally and given us so much of interest and value that this joint meeting will long be remembered as one of

our best, but you have created an insatiate appetite for more, and so it is to get the benefit of your knowledge and experience upon this subject that we contribute this paper.

250 South Twenty-first Street.

MENTAL DEFICIENCY AND CRIMINALITY.

By MAX G. SCHLAPP, M.D.,

NEW YORK.

Four hundred years ago, no less a thoughtful and scholarly personage than Martin Luther recommended that a twelve-year-old child be drowned and asked that prayers be offered to cleanse its soul of a devil. Coming nearer to our own time, our Puritan ancestors burned scores of persons so unfortunate as to be believed possessed of devils.

We know now that the child who almost fell victim to Luther's ignorance, and many of the persons burned by our forefathers as witches were guilty of no worse offense than feeblemindedness. We look back with wonder on the ignorance of these times; but our own attitude as evidenced by our present unenlightened methods of dealing with mental defectives, particularly those whose defectiveness has taken a criminal trend, shows in us a pitifully slow evolution in ascertaining the causes of abnormality in human beings.

We still judge criminals and delinquents by their acts alone and to a large extent dispose of them legally on this basis. The general public, and even the courts, believes that a person of normal intellect can control his actions and, consequently, that the actions of any person of normal intellect are premeditated, or at least controlled completely by the intellectual mental make-up, and that therefore the person is responsible.

In the light of well established facts, known to psychiatrists for the last half century, this method of placing responsibility for criminal acts is basically erroneous and should be revised. We must learn to comprehend many abnormal classes hitherto unrecognized by society as subjects for study, control or aid.

There is no question of altruism involved; a proper understanding and attitude toward these people who have no innate power of adjustment to their environment will make every home and family more nearly safe, the state's taxes will be lessened and future generations will be infinitely better equipped for the struggle of life. Too much stress cannot be laid on the broad scope of influence which mental defectives exercise on everyday affairs and the consequent tremendous interest the problem should have for "the man on the street."

You are acquainted—perhaps too well—with the boy who, surrounded by an affectionate family in a home of ease, runs away repeatedly, undergoes unnecessary hardships and when brought back can never give any explanation for his acts except that he "just wanted to get away." You doubtless also have come into contact with those other well-known types of juvenile delinquency—children who lie and practise petty thievery from their earliest years, later forge checks and generally involve their families in serious situations, and in whose genealogical history there is no discernible trace of family propensity for similar actions. There is also the brilliant youth with every promise of success and an intellect capable of splendid achievement who never quite gets a grip on himself, who follows the line of least resistance, becomes a drifter and eventually is classed as a confirmed failure.

In another class are the thousand of tramps, possessing what is commonly termed an aversion to work, who form an almost alien strata of society, useless to themselves, and liable at any time to become a menace to the communities through which they pass.

Still another class which we have not understood is composed of those unfortunate persons who because of abnormal emotional trends or phobias are forced to commit acts over which they have no intellectual control—such persons as, entering a subway or crowded hall, are subject to seizure by an overwhelming sense of oppression and an irresistable desire to rush out into the open, which they frequently do.

Even without the direct proof now offered by medical science, it should be obvious to any thinking person that in all these cases there is something wrong in the delicate mental mechanism which controls the destinies of these people. And there is just as much evidence that these mental disturbances are directly traceable to a physical cause.

Our present methods of handling criminals, not to mention our attitude toward all the classes of abnormalities mentioned heretofore, show an absolute lack of recognition of any connections between their acts and their mental and physical deformities.

The first thing to be understood about these people is the fact that the pathological criminal or mental defective is unable to adjust himself normally to his environment for the very important reason that the motivating activities of his brain are seriously disturbed.

To understand such disturbances, it is first necessary to know that the motivating activities of the brain are regulated entirely by two antecedent processes—the intellectual and the emotional, or affective, activities. If these two processes are well balanced, the motivating center will be stimulated in such a way as to make the individual adjust himself normally to his environment. Should this balance between the intellectual and the emotional processes be seriously disturbed, however, then it will be impossible for the individual to adjust himself normally and he will perpetrate acts which often are illegal and always abnormal.

The mind is thus a duality, and not a unity, and it must be understood as such if we are to gain a knowledge of its contents which will lead to a correct diagnosis of the conditions responsible for the maladjustment of individuals to their surroundings.

The intellectual side of the mind is that through which we receive perceptions and form conceptions. (See illustration.) Our standards of judgment are born, and the actual processes of reasoning take place, in this department of the mind.

Perceptions are the elementary mental impressions received through what commonly are called the five senses. Conceptions are the pictures the mind registers and files away of the things perceived.

For instance, a child sees a radiator. That initial impression of color and shape is a percept, as is the

impression of the sound the radiator makes. One perception goes into the brain through the projection centers of the visual nerves, the other through the projection centers of the auditory nerves. Together, the two percepts rush to the association centers of the brain and a concept of the radiator is formed.

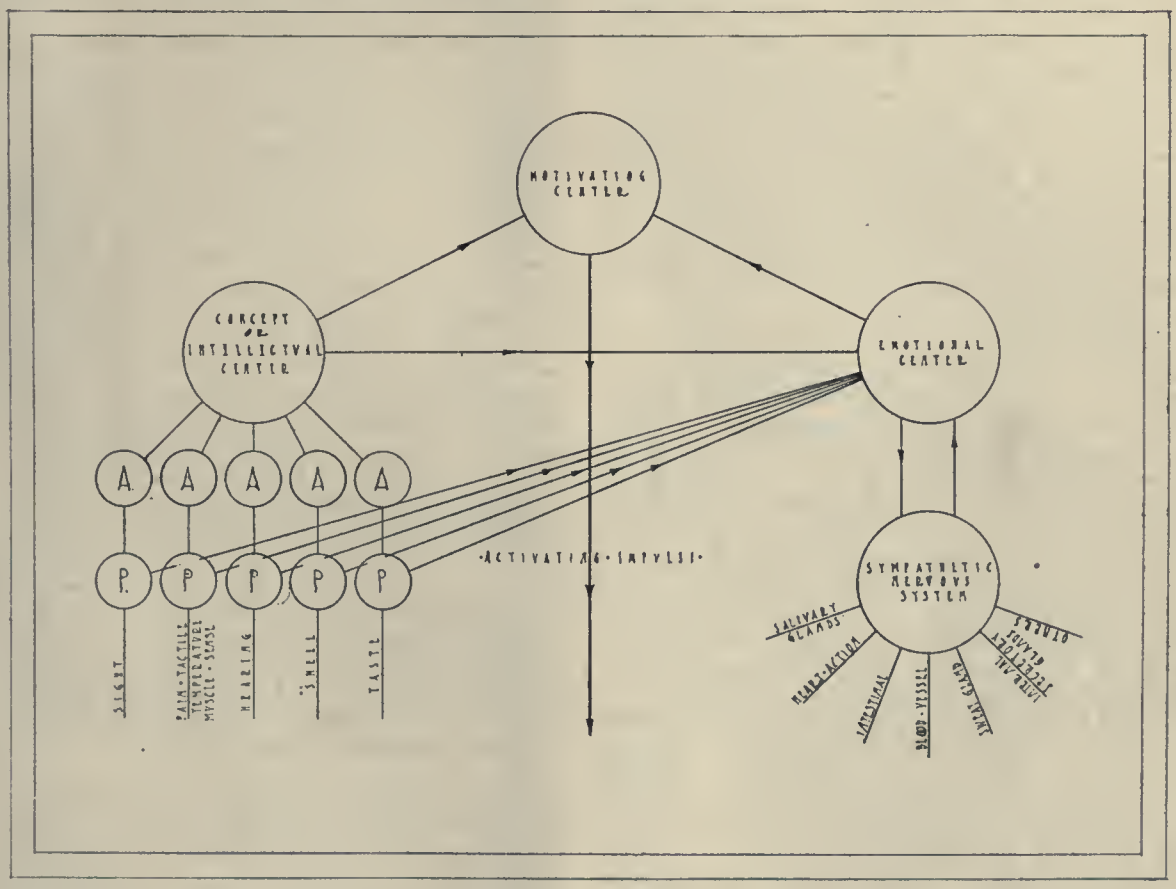
The child, still moved only by the intellect, is curious concerning the radiator—wants to know more about it. He reaches out and touches the hot metal. Another percept reaches his brain at once, the percept of pain, traveling to the pain centers. This percept goes also to the association centers and makes more complete the concept of the radiator. It is a thing which has a certain appearance, makes a certain sound and produces a certain variety of pain. The visual percept and the sound percept of the radiator may not have awakened any wave of feeling in the child's brain of which he was conscious, but when the percept of pain was added to the mental picture of the radiator, then, aside from the actual pain impression, a wave of feeling which was distinctly one of displeasure was awakened in the child's mental make-up.

From that time on, reception into the child's intellect of any of the three percepts will rebuild the completed concept, which will cause the emotional side of his mind to experience again the emotion of fear. The radiator may be silent, but the mere sight of it reawakens the concept and the child will not touch it.

Something else may make a similar sound. Until developed reasoning power teaches him better, the child associates the sound with the hot radiator and will not touch the object which produced the concept-forming noise. If he should run against something hot in the dark, the child will think of the radiator, provided he has not been burned by something else. In each case, the reawakened concept would arouse in the emotional centers of the child's mind the emotion of fear and that emotion would make him avoid the real or fancied danger.

Through this simple illustration, we see the relation between the two departments of the mind and the functional activities of each department.

A disturbance in brain activity seriously involving either the intellectual or the emotional centers, or both of them, results in what is known as mental defectiveness. To understand these disturbances, it is necessary to examine the life processes of the cells of which the brain, like the rest of the body, is composed.



We know that the life processes of the brain cells consist of three kinds of activity—the nutritive, the formative, and the functional. Through the nutritive processes, the cells take in substances from the surrounding medium and store them as potential energy. The formative activity is the process of cell-division, or physical growth. The functional activity is the process whereby a cell, responding to a stimulus from without, performs some act—the contraction of muscle cells, the secretion of gland cells, the reaction of nerve cells, and so forth.

The potential energy stored by the nutritive activity is drawn upon constantly by the formative and the functional activities, the two being rivals. Before birth, the cells of the body are chiefly engaged in formative activity, while from birth on the functional activity rapidly increases until it becomes the predominating process in adult life.

So, if the chemical substances necessary for certain cells are not supplied sufficiently before birth, or in early life, the growth of the organ those cells compose is affected. This results in physical defectiveness, or in mental defectiveness if the brain is involved. The same lack of nourishment in later life will affect the cells' functional activity, or their power to act.

A division of mental defectiveness into three groups provides the best working basis for grasping the intricacies of the particular branch in which we are interested.

In order immediately to dispose of it, the Traumatic Type should compose the first group. This includes all those cases in which the defectiveness is due to a definite physical injury to the brain before birth, at birth, or in early life.

Likewise, we should dispose of the Formative Type, or cases in which the brain in whole or in part has not developed because of improper cell growth.

The third, and to us the most important group because it is amenable to treatment, is the Functional Type. In cases of this type, the brain cells are not lacking in number, but there is a disturbance in the proportion of the different chemical factors in the surrounding medium from which the cells draw their necessary potential energy and activating substances, and therefore the cells do not react normally to stimulation.

The point at which an incoming impulse will explode the unstable protoplasm within the cell—thus turning the potential energy therein into kinetic energy—and release an outgoing impulse is called the threshold of functional activity. If there exists a normal chemical balance in the blood, and therefore in the cell, this threshold will be normal. If there exists a chemical unbalance or disturbance, then the threshold may be either raised or lowered.

Under conditions of chemical disturbance, this threshold may figuratively be compared to that of various grades of explosives. Gunpowder, for instance, is fairly stable, dynamite explodes more easily, and TNT has a still lower threshold.

It must be borne in mind that a normal threshold has a certain more or less constant level. If the threshold is raised above this level, the cell response is less active; indeed, the threshold may even be raised to the point where the cell will not respond at all to outside stimulation.

In a similar way, the lowering of the threshold below the normal level will bring about a condition in which the cell will respond to impulses that ordinarily would not cause a reaction.

One of the chief causes of a lowered threshold is a disturbance of the internal secretions. For example, a lowered threshold is found in persons in whom the thyroid substances of the body are increased. A marked instability of the cells is affected and explosive reactions will result from incoming impulses which in normal circumstances would hardly produce any reaction. Likewise, when the thyroid substance is deficient, a person will not respond normally and keenly to an incoming impulse which in normal circumstances would cause a response, because the threshold of functional activity has been raised.

What is true of the thyroid is also true of the suprarenal, pituitary, and other gland secretions, though their action has not yet been as fully determined as that of the thyroid.

Interference with the functional activity of the cells and emotional instability may also result from the introduction of foreign toxins into the system. These toxins may not only affect the threshold of functional activity but may also create a disturbance of the internal secretory glands.

Both toxins and the chemicals in the blood act selectively upon the various centers of the nervous system. Ether, for example, selectively involves the highest centers of cerebration, raising the threshold to such a point that incoming impulses cause no reaction, thus producing unconsciousness; but at the same time it does not equally affect the nerve cells of the respiratory and circulatory centers, thus permitting those centers to respond to incoming impulses and allowing the person to live.

So we see that a chemical disturbance in the blood may affect the functional activity of one or more centers of the brain, making them either more unstable, or stable. This brings us to consideration of the effect of such disturbances upon our actions.

Perceptions and conceptions, formed in the intellectual side of the brain, send impulses to the emotional side. If these impulses pass the threshold of functional activity in the emotional centers, a wave of feeling, or emotion, results. If, through a chemical disturbance of the blood, the threshold of functional activity of the cell groups of the emotional centers has been selectively lowered, the wave of feeling may be so strong as to wipe out entirely all restraining influences coming from the intellectual side of the brain, and make the emotional the motivating impulse in the person's mental make-up.

In persons of normal emotional make-up unreasonable reactions may be prevented through inhibitions coming from the intellectual side of the brain. In persons of unstable emotional make-up, intellectual inhibitions may be felt, but if the wave of feeling is strong enough the person may not even be conscious of the inhibition. The wave of feeling simply wipes out the mental attributes of judgment, of right, and of thought of consequences and precipitates the impulsively inspired action.

The person so unfortunate as to be unstable emotionally is not only exposed to these impulses, such as anger impulses, sex impulses, etc., and to the consequences arising from them, but any succession of exposures is likely to build up phobias and trends which may make him lose complete intellectual control of himself whenever the impulse comes to him.

These pathological waves of feeling, aroused by a percept or a concept, may be either negative or positive. A negative wave, which would be a displeasurable one, may create in the brain an unreasoning fear of some object or condition which will impel him against all his intellect to some unreasonable or perhaps ludicrous action, though one usually not of a criminal type. A positive, or pleasurable wave, on the other hand, may create in the brain a trend which will impel a man upon re-experiencing the concept to an action which is unreasonable and often criminal.

The boy in a comfortable home may be inflicted through unstable emotional make-up with a trend for running away and undergoing all sorts of unnecessary hardships; the boy who has all his desires

gratified may be inflicted with a trend to steal and eventually becomes a forger and thief; men of good training and intellect may come to commit heinous crimes; girls of good family and training may be led to the streets, and our reformatories, jails, and corrective institutions become constantly more crowded with persons who never should have been sent to them either in justice to themselves or to the rest of the community.

It should be emphasized that persons impelled by overpowering impulses that are not criminal have nothing to gain by their unusual actions; instead, they more often have much to lose by resulting ludicrous situations. Even those impelled to steal may in the next moment give away what they have taken. It is not as though they act for their personal benefit—they simply cannot help it.

Instances, no two alike, could be cited indefinitely, and the encouraging part of it is that most of these people can be relieved if not cured.

It is apparent that, if through tests we can find a chemical disturbance in the blood of persons of obvious unstable emotional make-up, we can lay hands on the seat of the disturbance in most cases and help them. In many of the cases examined at the Post-Graduate Hospital, chemical disturbance was found, and in more than half of these cases the cause was traced directly to certain of the internal secretory glands.

This has been accomplished through only a few blood tests which have been evolved. New tests are being worked on constantly, and the hope is to narrow the field until we can lay a finger on the seat of all emotional disturbances.

The large number of cases examined have given sufficient data to show a connection between emotional types and a disturbing of definite glands, and the attempt now is to establish a definite cause for each criminal type.

Necessarily the treatment varies in every case. It consists in most cases in raising the threshold of functional activity by chemical substances which prevent excessive stimulation of the internal secretory glands and by neutralizing the effects of certain excessive secretions by introducing counterbalancing substances.

The principles of the counterbalancing substances are found in animal glands, but these for the most part also remain to be determined with any degree of precision.

Where the disturbance is of thyroid origin, methods have been fairly well worked out, and there has been some success with suprarenal unbalances, but the pituitary and other glands have not yet revealed their secrets.

Based on the rapid strides made since this particular study was begun in 1912, there seems to be no limit to the possibilities which the research of the next few years may open. The key may safely be said to have been found and the lock turned; it remains to discover what lies beyond in definite methods of diagnosis and treatment.

Means for this research, so vital for the protection and welfare of every home, are not now at hand. Such institutions as we have were designed and established for the most part only for segregation or punishment. There is no provision for the necessary constant observation and treatment.

It is foolish to build institutions for detaining defectives for long periods as a punishment for a condition for which they are not responsible, and then discharge them without doing anything to remove the cause of their trouble. Every person handled in this manner is not only an expense to the State, but he is made a potential menace to the State. His emotional instability lays him wide open to all sorts of concepts and impulses from intellectual criminals.

The attitude of the public and of the State toward the social problem must be changed if conditions are to be improved. Hospitals must be substituted for prisons and treatment for punishment, so far as defectives are concerned.

Then there will be a real chance to combat the problem of crime. It will be possible to separate those who are not responsible for their misdeeds from those who are; and this latter class, who use a perfectly ordered mind to prey upon society, we shall come to incarcerate permanently, instead of inflicting upon them punishment which may not prevent a repetition of their criminal acts.

The first step in introducing this order should be the erection of a Detention Hospital where all persons suspected of defectiveness can be properly examined and their condition ascertained. There should be the closest of contact between this hospital and the courts and other public institutions.

The proper execution of tests requires periods of fasting, quiet, and observation, which cannot be observed unless the patient is detained.

For this reason, and because of the many other activities of the Post-Graduate Hospital, the work now being done there is greatly handicapped. This work is to be extended in the near future as part of the expansion program for which the Post-Graduate Medical School and Hospital is raising an additional $2,000,000 endowment, but even this will not be sufficient for exhaustive investigation.

Besides reception and consultation rooms, wards, recreation, and living quarters, such an institution as would meet the requirements must have laboratories fully equipped both for complete tests and research. Every provision should be made for prompt and thorough examination by a staff of specially trained observers and nurses and there should be either a sufficient endowment fund or an assured appropriation in order to prevent embarrassment in management, or limitation in the scope of work.

This may sound like a large order, but to every thinking person it must be evident that the solution of society's gravest problem, which is criminality, cannot be accomplished without the expenditure of much time, thought, and effort, and that these are made possible only with money. Such funds as would be required, on the other hand, would amount to the smallest fraction of the money now spent in the well-intended but misdirected efforts now made by society to cope with an ugly situation.

It may be that private philanthropy once more will blaze the trail of progress, but that time surely cannot be far off when the State will avail itself of the more humane and common-sense methods which science has to offer in the care of the helplessly unfortunate.

40 East Forty-first Street.

THE DUCTLESS GLANDS AND CONSTITUTIONAL DIAGNOSIS.

By JACOB GUTMAN, PHAR.D., M.D., F.A.C.P.,

BROOKLYN, NEW YORK.

DIRECTOR DEPARTMENT OF MEDICINE AND ENDOCRINOLOGY, BROOKLYN DIAGNOSTIC INSTITUTE.

It is the aim of this paper to call attention first to a number of physiological facts serving as a basis upon which the study of human constitutions is founded, and second, to enter a plea for the diagnosis of morbid phenomena from an endocrine standpoint as the only method by which the obscure paths of the unexplored symptomatic wilderness may be illumined.

In the interpretation of a case from the constitutional standpoint several fundamental facts concerning the functions of the ductless glands upon which the study of human constitutions is based must be borne in mind: (1) The effect of the inherited powers of the endocrines upon the development of the individual; (2) their control of all metabolic processes of fundamental importance; (3) their domination of all vital functions occurring during the three cycles of life; (4) their cooperative method of functioning and intimate relationship; and (5) the consequences resulting from a derangement of their functions or of glandular dyshormonism.

Inherited Endocrine Powers and Development.—As to the first, the influence which the inherited valencies of the endocrines exercise upon development is conclusively evident so that all may read who understand the sign manual. It begins with the very origin of life and terminates only at its end. From that moment when the spermatozoon penetrates the micropyle to fecundate the ovum, the fate of the future being is forever sealed and destined. Every particle of protoplasm, every granule of the impregnated ovum carries within it the essence of the parental ductless glands and with it all those elements which transmit to the offspring the racial, national, and atavistic characteristics of its progenitors. They endow the child with all the phenomena we commonly interpret as inherited. They determine those features which identify the offspring in later life as Caucasian or Mongolian, Scandinavian or Italian, Gentile or Jew. They serve as foundation stones upon which the future tendencies, mental expressions, and pathological affectations are built. They determine the unique facial features, the habits, character, traits, ambitions, talents, longevity, and idiosyncracies peculiar to families and individuals. This is due to the common orchestration of the ductless glands in all members of a family; their endocrines are of similar morphological structure, of like functional capacity; they exert their influences in all members of the family in parallel directions and proportions.

That the conformation of the individual and his organs is within the control of the endocrines has not only been conclusively proven by experimentation but repeatedly verified by clinical investigation. Fraenkel has enabled us to classify three main types of endocrine constitution which Kaplan calls tropisms: namely, the thyrotrope, adrenotrope, and pituitotrope. Individuals of the pure type are common, but more common are those of mixed type. In the pure types only one of the endocrines exercises a dominating influence in development. It requires no assistance from the others. It is the commander in chief of the forces engaged in building the individual. It is capable of meeting every emergency. It creates its own type of man with the functions, habits, and attributes peculiar to itself. A thyrotrope differs as much from an adrenotrope as does a greyhound from a bulldog. Both are animals, of the same genus but of different species, however. The greyhound is unique in size, character, form, and ambition and likewise the bulldog, but with qualifications quite different. Each is destined by nature for different careers. The same applies to human beings. The pure thyrotrope is easily distinguished from the pure adrenotrope, and the adrenotrope from the pituitotrope. Each is peculiar in build, height, skin, hair, mental capacity, character, ambition, and predisposition to certain diseases.

The mixed types are less clearly defined than the pure, and are more difficult to classify. The mixed trope is a hybrid in whom two or even three of the endocrines constantly strive for predominance with a resulting confusion in developmental characteristics and attributes, thus necessitating a hyphenated or mixed classification. One of the glands, the thyroid, for example, may show its inherent effects by the presence of many thyroidal markings originating at a very early date in development, while other features will disclose the influence at a later period of the pituitary or adrenals. This combination stamps the individual as a thyropituitotrope or thyroadrenotrope.

Substantial evidence that the endocrine glands are in full control of the external features of the human being is also supplied when the glands are pathologically affected. The morbid phenomena which we were taught to look upon as hereditary are such because they affect only individuals of similar glandular structure and function or tropism. The study of the relationship of the endocrines to pathological states by Leignel-Lavastine and others has proven quite conclusively that certain diseases affect only certain individuals of a certain definite constitution. It is a commonly known fact that apoplexy, diabetes, arteriosclerosis, and interstitial nephritis are met with almost exclusively in individuals of the so-called status apoplecticus and seldom occur in the thymicolymphatic. On the other hand, anemia, tuberculosis, hemophilia and lymphatic-gland diseases occur in the thymicolymphatic and not in the apoplectic. The two individuals are very dissimilar in their constitutional fabrics, being of different endocrine tropism. Two beings of the same genus *Homo*, but of different breeds, of unlike physical and mental capacity. This fact is of practical value in the diagnosis of pathological conditions because it shows the definite relationship of the constitution to its peculiar form of morbidity, whether functional or pathological, and suggests the possibility of an individualistic and accurately scientific therapy as an improvement upon and substitute for polypharmacy, empiricism, and therapeutic nihilism—conditions for which we are often condemned

by the intelligent layman and ridiculed by the unscrupulous healers of every variety, and which are a constant source of humiliation to every sensible and intelligent member of the profession.

Endocrine Control of Metabolism.—Another fact to bear in mind in constitutional analysis is the control of metabolism by the endocrine glands. Through such control the growth and form of each and every organ are regulated. By enhancing and retarding metabolic changes the nutrition of an organ is favored or restricted. This results in an increased or diminished growth of the particular organ. Whether an individual is to be tall or short, lean or corpulent, graceful or awkward is all dependent upon the peculiar reaction of the different glands individually and collectively; upon whether they work together harmoniously or discordantly; upon which does most work or which one relaxes in its functions.

The influences upon growth are exceptionally potent when for any reason a gland undergoes morphological changes with either a hypo or hyperplasia of certain of its elements. As a consequence marked changes occur in its functions producing phenomena illustrating in a striking manner the powerful effects of such alterations of function. Every one is more or less familiar with the remarkable changes in growth, mentality, and sexuality displayed in an individual affected by an overgrowth of the anterior pituitary and known as acromegalic. We see the marked differences in the metabolic rate, sugar tolerance, oxygen consumption, and urea excretion between an exophthalmic and a myxedematous individual. The striking abnormality of a eunuchoid or Froehlich type individual is so marked that it is apparent even to the layman. It is often astonishing to see the marked transformation which can occur in an individual as a result of perverted endocrine function. Normally, each endocrine is endowed with definite functions which in accordance with a prescribed rate of metabolic exchanges determine the physiological activity of the organism. Under abnormal conditions, the metabolic rate is altered, some functions are augmented and others decreased, and metabolic imbalance occurs.

To illustrate: the thyroid regulates the shape, form, and finish of the organ. The pituitary determines the period when certain developmental events are to occur: the time of teeth eruption, of puberty, of the menstrual cycle, of the onset of labor, etc. The gonads are empowered to distribute the secondary sexual characteristics, to determine masculinity and femininity, sexual maturity, and skeletal peculiarities. Abnormally, all the above mentioned functions of the several glands assume different aspects. An individual so affected apparently changes into a different subject. He changes in growth, the shape of his extremities, the size of the various acral parts, and character, habits, mental aptitude, disposition, etc. also become altered. These transformations may be slight or of marked degree, depending entirely upon the extent of the changes in the affected gland. They are always demonstrable by careful examination even when of slight degree.

The Domination of Vital Functions.—All vital functions instrumental in the maintenance of life are directly initiated by the endocrine glands. It has been shown that the adrenals have the closest anatomic and embryologic connection with the sympathetic system. Wherever ganglionic nerve cells and fibers are present, chromaffine cells analogous to those in the adrenals are also to be found. Embryologically, these two tissues are the descendants of the same mother cells and wander from their seat of origin into distant regions, side by side, and closely associated anatomically and functionally. The hormones of the endocrines are in constant touch with the whole vegetative system, those of the adrenals influencing the sympathetic while those of the pituitary seem to activate the parasympathetic. The adrenal hormones activate the nerve cells in which the energy is stored in a static form. Such activation converts the static forces into a kinetic expression which results in a discharge of energy through organs controlled by the cells activated.

All impulses are derived from the external world through distant and chemical contact, ceptor stimuli, as Crile calls them. Such stimuli call for immediate response on the part of the adrenals which instantaneously mobilize their hormones to such parts of the organism as are called upon for activity in response to the original impulse. Perhaps an illustration may help to explain the mechanism more clearly. A cat unexpectedly sees a dog. The sight of the enemy brings to the cat's consciousness a vivid picture of danger. Through eons of ages the cat and dog families were enemies, and the mechanism of offense and defense were always brought into play when chance brought them together. The visual mental picture reflected upon the cat's brain impresses the necessity for either defense or flight. For either of these force is necessary. Static force is stored up in the muscle and nerve cell. The biologic mechanism whereby consciousness dictates an order requiring execution is directed to the adrenals where the activating hormones which convert the static into kinetic energy are stored in sufficient quantities to meet all emergencies and activities in the life of the animal. Vasomotor energy is also known to be concentrated to a greater extent in the adrenals than elsewhere. By various efferent paths orders are issued to check immediately all immaterial activities in organs not called for in the defense or flight of the animal. Thus, gastric digestion, intestinal absorption, sexual activity, and similar functions are stopped while all material such as glycogen, oxygen, etc., necessary for the most strenuous functions of the defensive organs, is mobilized through the agency of the vascular and nervous systems to the organs concerned in the defense. A full current of adrenal secretion, nutritious materials, glycogen, oxygen, etc., is thus encountered in the blood stream flowing to the defensive organs of the animal. Thus, the cat's brain is forced into full action, the mind is cleared from all immaterial thoughts, the sight is sharpened, the hearing made most acute, the cardiorespiratory apparatus prepared for forceful action, the muscular apparatus loaded with kinetic force, and prepared to spend it all in the struggle for life. All this is accomplished primarily, through the medium of the vegetative, nervous system.

All systems of the organism are directly controlled by the vegetative nerves and indirectly governed by the forces higher up, the endocrines. Thus the cardiovascular, gastrointestinal, vasomotor, respiratory, sexual, and other systems are fully subservient to the glandular hormones. Every phase of life, every material function, every physiological act occurring within the sphere of these systems is regulated and controlled, induced or checked, by the hormones of some one endocrine; every functional expression is not an accident but a corollary of endocrine expression. Bradycardia or tachycardia vascular hyper or hypotension, hypertonus or atonicity, constipation or diarrhea, gastric hyperacidity or achylia are not mere coincidences but consequences of endocrine management through the vegetative nervous system.

Endocrine Cooperation.—Another principle to remember is the interrelationship of the endocrine glands and the cooperative system of their functioning. Although certain definite glands assume at certain periods of life a leading rôle in the development and physiological interpretations of the organism, all others, however, are at all times cooperating harmoniously with the leader. Such united action is necessary to keep the individual in perfect balance and to serve his economy best. The leading gland determines the architecture and creates an individual of its own type. The others assist in this work. Harmony prevails at all times under normal conditions. If, however, one of the glands, because of special stress becomes exhausted and unable further to respond to its task, the others hasten to its rescue and assume its responsibilities. They call for a hyper or hypofunction of the organs under their own control to make up for the deficiencies of the organs controlled by the exhausted gland. Such cooperation, if perfect, preserves a normal balance.

Standards of good health differ, no standard may be proclaimed normal, to the exclusion of all others. What is normal for one individual need not be for another, for it is his habitus and subjective state which determine what is normal or abnormal for him. Hypertension, high acidity, or marked trichosis may be the nearest possible approach to normal in one case and yet decidedly abnormal in another of different tropism. It is essential for good health that there should exist perfect cooperation of the various endocrines and any interference or disharmony in the cooperation, whether through exhaustion, disease, or ablation, is certain to be followed by serious consequences.

Dyshormonism.—Another fact to be borne in mind is the change produced in an organism whose ductless glands functionate deficiently. Individuals born with defective glands show most decided morphologic and physiologic distortions. In those, on the other hand, in whom the glands become affected later in life, the symptoms depend entirely upon the degree of glandular involvement. If the damage to an endocrine is not of an irreparable nature, the others may for a certain time compensate for the deficiency and overcome the difficulty with but few signs of disturbance. If, on the other hand, the damage to the gland is extensive, the resulting deformities may be extremely marked and severe. However, glands need not be incapacitated in all of their multiple functions. They may fail only in some of their valencies and remain competent in others. Failure of a gland may occur at any period of the three great cycles of life. All events from childhood to senility call for special efforts by at least one of the endocrines. The demands may overstimulate or exhaust a gland depending upon the amount of stimulus and the glandular capability; hence, some of the glands may withstand the strain of life and functionate during the entire life of the individual, but a gland of inferior quality may fail completely with the resulting symptoms of dyshormonism. School life, infectious diseases, puberty, courtship, marriage, childbirth, dissipation, accidents, privation, financial reverses, mental strain, etc., may be the rock upon which the constitution of an individual with deficient endocrines will founder. Milder efforts may cause only temporary exhaustion from which the gland may recover, but if the strain is carried to extremes, a permanent exhaustion will occur from which the gland may never recover. This results in a perverted metabolism with characteristic subjective and objective syndrones now recognized as a state of dyshormonism.

Constitutional Diagnosis.—Since the endocrines exercise this profound influence, it is essential in the constitutional analysis of a case to bear in mind all past events and their effects upon the individual. The events of infancy, adolescence and maturity, the sexual life, nutrition, vocation, etc., always disclose points of scientific interest and facts of etiological importance. In addition, we must bear in mind the inherited tendencies, for these also make an indelible imprint upon the constitution and help to bring about the conditions for which the patient comes to us.

A case may be studied from a number of viewpoints. The pathological, at present the predominating method is interesting, useful, and practical, but it is never fully illuminating. It fails to throw light upon many functional disturbances met with in the study of the patient and does not satisfy the physician who seeks for a complete understanding of the case. A pathological diagnosis can be obtained only after a rigid clinical examination, various laboratory analyses, the *x*-ray, etc. After having conducted the patient through all these and having obtained important and necessary information, are we then really in possession of all facts relating to the case? Are we prepared to answer all questions which the inquisitive mind might ask? Have we found an explanation for all functional disturbances? Have we disclosed the primary fundamental cause of the pathological process? Have we discovered the reason why the individual symptoms of one differs so decidedly from the complex of another with the same pathological diagnosis? We have not! True, after an exhaustive examination we are privileged to label the patients with the name of some disease but should we, as scientific, conscientious physicians, be contented with this? No, we should demand an explanation for all and everything we perceive. We want to know why individuals affected with similar pathological derangements present dissimilar symptoms. We want to know why some of our pneumonia cases run a very severe and fatal course while others a

mild and favorable course and why certain typhoid patients suffer grave abdominal complications while others show marked cephalic manifestations. What determines the variety of influenza in an individual? Why do certain people suffer from asthma, diabetes, hay fever, nephritis, etc., and not others? What predisposes some of our children to numerous infectious diseases while others living under the same environments are free from any? Why is immunity so benevolent to some individuals and not others? Similar innumerable questions crowd the mind of the doctor who studies his case in a critical manner. Can he find an answer to all this from a pathological analysis? Certainly not! We seek for an explanation in the literature and text books but in vain. Our text books in describing the numerous pathological affections usually excuse our ignorance of the many problems in medicine by the adaptation of the word "unknown" and admit that the symptomatology of the same disease may differ decidedly in different individuals but offer no explanation for the discrepancy.

The pathologic, anatomic, chemic, and all the older methods of diagnosis supply very valuable data which permit the elucidation of many features of a case but only of those which are of a static character. These represent finalities. They do not tell us of the various steps and changes which the organ had suffered before its conversion from the normal to the pathological. In other words, all dynamic events which have occurred during that period of transformation from normal to abnormal are not elucidated by a pathological study. Formerly, when a patient applied to his physician complaining of symptoms for which even after careful search, no pathologic basis could be disclosed, the doctor was apt to consider the patient either as a neurasthenic or as hysterical and eventually as more or less of a nuisance. We were unable to identify such complaints with disturbed physiological function of certain important organs before their conversion into distinct anatomically recognized pathological states. We were unable to perceive the close connection between subjective symptoms and pathological physiology. Now, since the endocrines have received close study and since constitutional diagnosis has taken a place in the foreground, the physician begins to see light and to perceive a basis even for the multitude of symptoms which the so-called neurasthenic displays. It is quite a revelation to discover how valuable, how interesting, and how illuminating constitutional diagnosis on an endocrine basis is, especially so since it forms a basis for the more rational study of therapeutics.

Since endocrinology has received the attention of scientists, another milestone has been added in the progress of diagnosis and therapeutics. It has placed the practice of medicine nearer to the exactness and explicitness of a science. It has furnished the means of understanding many of the functional phenomena hitherto not understood. It has created a new physiology and has displaced pathological diagnosis as the primary and most important factor of the proper understanding of disease. Even now, in the early stages of the science, endocrinology answers most of the questions which have been just propounded.

Endocrinologic diagnosis is not a simple procedure, but it helps, one to decipher the whys and wherefores of life and offers a precise and more satisfactory explanation of conditions not otherwise satisfactorily explainable. It renders possible individualization in diagnosis and therapy, whereas in pathological diagnosis alone, individualization is impossible. This accounts for the fact that therapy based solely upon pathological findings is seldom productive of any very definite or lasting curative results. For these reasons and from the standpoint of the sick individual, correct endocrinological diagnosis must be the chief aim of the medical diagnostician of the future.

867 St. Marks Avenue.

MENTAL HYGIENE DURING CHILDHOOD.*

By IRA S. WILE, M.D.,
NEW YORK.

THE popularity and the extent in development of various mental cults offer a challenge to the medical profession. Laying aside any spiritual significance which they may claim, one is obliged to believe that they supply to their devotees an element that increases their happiness and fortifies their resistance against morbific factors threatening their peace of mind. In a sense their existence is the result of the neglect of medicine to recognize human unity and the reciprocal relations of physical and mental functions. Waving metaphysical conceptions, man is more than a mere system of anatomical parts. The single transition from life to death indicates an alteration of existent characters far beyond present laboratory demonstration. The physical body apparently remains, but at the moment of exitus, some vital force has ceased to exist. Similarly, one notes what is termed "physical perfection," in the presence of psychic disabilities, varying from hyperirritability to insanity. The entire field of the psychoneuroses reveals a little understood relationship between the physical manifestations of mental disorder, and the peculiar psychic distortions acting as an electric spark, short-circuiting comfort and efficiency.

Pediatrics, as a branch of medical science, has concerned itself principally with the body, as differentiated from the mind. There has been a certain degree of recognition of the fact that bodily states affect the mind and partially determine personality and character. The numerous functional disorders of childhood attest the marked influences of environmental experience upon bodily function and demonstrate the necessity for increased attention to a study of childhood in all its phases. How infrequently is attention focused on the normal instincts of childhood as a means of interpreting variations in conduct that are deemed pathological and that have their origin attributed to single physical defects, such as hypertrophied tonsils, or phimosis! Without marshalling statistics it is undeniable that a large percentage of the mental disorders recurring during adolescence and maturity have their roots in the variable soil of childhood. Much of the communal cost of insanity, crime, vocational failures, dependency, and suicide could be

* Read before the Yorkville Medical Society of New York, Dec. 15, 1919.

avoided through a larger degree of heed to the hygiene of childhood.

It cannot be overemphasized that emotions and ideas are as profoundly effective of physical changes as many of the drugs now employed for therapeutic purposes. The effect of emotions upon the visceral, motor, and nervous systems is only partially appreciated. The part that ideas play in motivating and energizing life is scarcely comprehended, though their importance is intensified by virtue of their recurrence and possible permanency. The profound effects of emotions and ideas combined are readily realized with the acceptance of the pleasure and pain principle so long regarded as the mainspring of human conduct.

The prevalence of insanity, hysteria, the psychoneuroses, and, indeed, delinquency and maladjustments during maturity may be attributed in part to our failure to grasp the importance of attacking their origins during childhood. Altogether, inadequate thought has been devoted to the beginnings of mental disorders. Stress has been placed upon alcoholism, suicide, vicious inheritances, and syphilis without a deeper investigation into the various causes underlying them.

The elements entering into hygiene during childhood comprise the many factors influencing child welfare. These include heredity and the essential phases of the environment that are involved in the family, companionship, school influences, recreational opportunities, and the complete special environment surrounding the individual child. There is a particular need of considering all these in connection with the development of healthy childhood, because of the peculiarly altered ratios of childbearing. To-day, the highest birth rate is found among racial elements that have contributed the least toward racial betterment. Furthermore, social agencies and the humanization of health administration have caused a high degree of reversal of the old theoretical law of the survival of the fittest. Modern methods have acepted offspring and have promoted their survival regardless of their potentials. As a result, not merely are an increasing number of the unfit demanding prolonged nurture, protection, and healthful development, but the community finds itself charged with an increased responsibility for its own protection. It is necessary, therefore, for society to differentiate particular elements of its population in order that the essential types of hygienic, educational, social, and administrative agencies may be applied in the interest of communal betterment and protection.

To term traits "hereditary" is simple, but unsatisfactory if it involves a sense of finality. Patently, the child receives no benefit from the diagnosis of an inherited defect. The solution of such a problem is forced back to the treatment of our present problems concerning marriage. If one believes that children inherit tendencies toward specific defects, then it is essential for the salvation of the child that its developmental training and environment be such as to preclude the full evolution of the suspected handicap or peculiarity. It is for this reason that the mental hygiene of childhood embraces all phases of the relations of childhood reacting to its environment. It is well understood that the fundamental factors of mind training and conduct are perceived and absorbed through environmental contacts whether of a personal or a communal nature.

The interest of the child is not always the interest of society. Conduct is action directed toward the realization of desires born of self-interest. It is apparent that the social problem is to make self-interest include social interest. In a sense not strictly Freudian, conduct arises from the expression of the self-preservative, or ego instinct, and the race preservative, or sex instinct. The more nearly these two approach harmony the higher is the ideal and the more social is the character of conduct. It is evident that in securing the fusion of these two instincts, rational and character-building contacts must be derived from the manifold elements of the environment.

The child forms only one part of the problem of childhood. Just as infant mortality has been reduced through the correction of social defects and delinquencies, so mental morbidity and mortality may be reduced by directing attention in a constructive manner to the environmental components moulding the minds of children. The tendency to place all the blame upon the child has been due to our failure to understand the importance of causal factors originating outside of the child's mind, involving undesirable reactions. The frequency with which children are called lazy, foolish, vicious, and "no good" is indicative of the measure of placing full responsibility for conduct and character upon children, regardless of the fact that they may be suffering from an iniquitous parenthood or an uncharitably repressive environment.

Mental hygiene, therefore, may be regarded as involving physical, psychological, educational, and social factors. One recognizes immediately the difference in hygiene that is to be found in superior and in inferior homes. One grasps the possibility of the mental conflicts that may arise under a system of rigid discipline that attempts to force adult standards upon youthful minds incapable of appreciating or accepting them. One can see the possibility of repression from physical causes, such as insufficient oxidation, impairment of sight and hearing, or physical deformity. No imagination is required to visualize the psychological influences of praise or blame, nor is there difficulty in recognizing the harmful results of educational maladjustments, whether they are due to inherent mental defects or to the faulty gradation in school of the child with superior mental ability. It thus becomes evident that the supplying of information relative to the necessary mental hygiene during childhood requires the study and investigation of the physical, psychological, educational, and social factors. It is not possible to diagnose the causes of irritability, emotionalism, obsessions, prejudices, and fears in terms of physical defects alone, nor is it sufficient to attribute them to functional disorders, the anatomic causes of which are undefined. These symptoms, however, are highly suggestive of mental disorders, which either may crystallize into powerful impulses leading to inefficiency, suicide, or crime, or may continue to exist in the form of hysteria or neuroses causative of vocational ineptitude predisposing to dependency.

At the present time one-third to one-half of

school children fail to move through schools at the expected rate of progress. Ten to 15 per cent. of the children are two years or more retarded, and 5 to 8 per cent. are retarded at least three years. What is the reason for this educational failure? The explanation is not to be secured through physical examination, despite the fact that numerous defects are discoverable. A psychological examination aids in determining the level of intelligence and permits the school adjustment of children in greater conformity with their educability. Mass education slowly is giving way to special types of classes more adequately attuned to the mental vibrations of children, differing widely in their educational possibilities. School failure has not been due so much to the mental weaknesses of children as to the rigidity of school systems aiming to impress a single mould upon minds varying in plasticity. The individualization of educational opportunities, direction, and methods is an ideal difficult to achieve, but is, nevertheless, of practical importance in determining the hygiene of mental development. Mental weakness in some particular way merits careful study. Why is one child an adept in spelling and a failure in arithmetic? Why is another gifted in the art of acquiring languages and completely at a loss in manual work? Why does a third child learn more easily through visual methods and still another through aural measures? These problems exist, and in individual children some solution is required. The large number of school failures who have achieved success in the world points out the necessity for scrutinizing the educational problems presented by children with a view to securing a more rational adaptation of mental ability, general and special, to educational facilities.

It is equally valuable from the standpoint of the school system to differentiate physical defectives from mental defectives, and to appreciate the causes underlying backwardness, truancy, and incorrigibility. The gain to the family is similarly important, while it is assuredly a benefit to children to be understood, whether the cause of their educational failure be diagnosed as imbecility or resentment at pedagogical injustice.

The child with superior intelligence and a high intelligence quotient is entitled to have its mind supplied with adequate exercise just as much as is the child of inferior mental power to be granted a modification of the curriculum, according to its needs. The time marking system for the bright is mentally harmful, and, racially considered, is more so than is the alleged forcing of children with inferior intellects. Nature in her wisdom has afforded the average child an ample variety of mechanisms enabling it to escape overwork.

Without enumerating all the sins of omission and commission in our educational system, it is sufficient to insist that physicians should be aware of the significance of the physical, psychological, educational, and social factors with a view to studying them and applying their knowledge to the preservation of child mentality, and the elimination of such symptoms as tend to mental deterioration and social impoverishment. The school system deserves no greater criticism than the medical profession, which has failed to offer its advice or insist upon a more elastic scheme of mind training.

A consideration of mental hygiene during childhood involves the recognition of the numerous problems bound up in present-day discussions of defectives, delinquents, and dependents. The recognition of mental dullness and feeblemindedness and its distribution among idiots, imbeciles, and morons is of primary importance. Childhood must be understood in order to be adequately supervised or directed. Educational possibilities are not determinable without an insight into latent mental power. The part that mental defectiveness plays in delinquency and dependency is of too great importance to warrant its neglect. The share that delinquency claims in the development of dependency is also of considerable interest. I purposely omit the statistical phases of my argument because the facts are patent, and reliable figures are available to all desirous of obtaining them. It is, however, of the utmost significance that the modern management of juvenile problems is based upon the study of the mind, with a view to interpreting conduct in terms of intelligence and motivation. Dependency, similarly, is being restudied with relation to the mental characteristics of specific members of the household. Vocational adjustment is undergoing numerous alterations through the interposition of psychological methods in vocational guidance and labor management. The school systems are being altered to meet the needs of childhood as revealed through the study of mental makeup.

It is evident that the fundamentals of mind training must include an increasing attention to mental adjustment to the realities of life, and this requires the institution of a wider measure of mental hygiene. It is insufficient to use the word nervousness as a satisfactory explanation of children's conduct, nor is it scientific to be satisfied with an explanation to parents that a defect is trivial, and that the child will outgrow it, usually it may be remarked, within the mystic number of seven years. Many of the conditions regarded as nervousness find their origin in physical, emotional, or volitional disturbances. Let us, for example, bear in mind such conditions as stuttering, tics, restlessness, easy fatiguability, peevishness, bashfulness, fears, night terrors, sexual perversions, suggestibility, vacillation, hysterical laughter, chronic headaches, irregular attacks of indigestion, lack of self-control, sulkiness, moroseness, so-called laziness, stubbornness, and stupidity. These are all conditions which are far from uncommon and present difficulties which are not surmounted by fixing upon nervousness as a cause. Why do children present these symptoms; how may they be corrected, and, what is of greater value, how may they be prevented? These represent some of the questions for which mental hygiene seeks to offer a partial solution. Investigation of children possessing such defects and handicaps reveals the necessity of studying the physical, psychological, educational, and social factors entering into the reactions of childhood.

Mental hygiene is not concerned with the study of memory or perception or reasoning and judgment, as such, in terms of clinical psychology, but is seeking to understand the whole child, as a hu-

man being that forms part of organic society. It recognizes the instincts, volitions, and emotions and all other bases of character as plastic material varying in potential development, whose mature form will bear the imprint of the countless moulds into which it is cast.

Mental hygiene should begin theoretically with selective matings, but at this time progress in this direction is limited to the prenuptial guarantees, the segregation of the feebleminded, and some abortive efforts at sterilization of epileptics, criminals, and the insane. In a sense the efforts at prenatal care, improved maternity facilities, the emphasis upon a decrease of the unnecessary use of forceps, and the extension of infant welfare work are to be regarded as phases of work in mental hygiene. It is true that the efforts toward the child are largely by indirection, the stress being placed upon the care and education of the mother, in the interest of the welfare of the child. During infancy, for example, efforts are made to attack many undesirable infantile habits, including thumb-sucking, masturbation, and the like, though the burden of effort rests upon the parent.

Infancy, in a nonlegal sense, gives way to childhood at about the age of two years, and the paucity of agencies dealing with the preschool age has left this period of life somewhat barren of study as to the necessary provisions for systematic hygienic care, particularly in the mental field. Only the occasional problem arising during these years receives the necessary and merited study at the hands of the regular medical attendants. Carelessness, indifference, and ignorance have been responsible for failure to give sufficient thought and study to mental development, character, and conduct before the school age is reached. Under these circumstances the majority of children enter school handicapped physically or mentally, or with both defects working to interfere with school progress and the development of those attributes deemed essential for units that are to participate in citizenship and government. A large measure of the school failures, destroying self-confidence and instilling a sense of inferiority, might have been obviated had thought been given earlier to the welfare of the children. I shall not dwell upon the numerous types of efforts that are undertaken during the school age, though I wish to emphasize the tremendous wastage of time, effort, and money which results from the failure to attack the problems of childhood previous to entrance into school.

In order to institute mental hygiene in a practicay way, it is essential that physicians enter into the spirit of this new movement to promote mental health. It is obvious that a complete physical examination should be made and, as early as may be possible, all correctible defects and handicaps should receive the necessary attention. In this connection particular stress is to be placed upon nutrition, vision, hearing, tonsils, adenoids, and teeth, though, of course, there must be no overlooking of disturbances of the circulatory, respiratory, excretory, or nervous systems.

The removal of physical defects is essential not merely because of the physical benefits that result but also as a means of supplying the sound body, which partially conditions the sound mind. Its value is emphasized in connection with so-called borderline cases which test the skill of the psychiatrist and require careful and prolonged study in order to determine whether the preponderant influence lies in the physical or mental sphere.

The tendency to make rapid diagnosis is unfortunate and fails to take into consideration the baneful effects upon mentality of deficient oxidation or malnutrition. The difficulties of mental diagnosis during childhood, particularly in the line of determining psychopathic children, demand the scrupulous care of the body as an adjunct to the investigation of mental development.

The second step to be taken involves the mental examination. For this purpose I employ the Stanford revision of the Binet-Simon tests, which suffice to give an idea of the general level of intelligence. It is insufficient, however, to rest content with the determination of the intelligence quotient, because this is little more than cataloguing mental levels. It fails to take into consideration various mental complexes which determine the form and development of character and conduct within the demonstrated sphere of intellectual capacity. The necessity of examinations beyond the determination of intelligence levels is emphasized in the psychiatric problems of the juvenile courts, and particularly in such studies of the mental mechanism of criminals, particularly recidivists, as have been portrayed by Dr. Glueck.

There are varieties of mental powers which demand specific study in order to determine the directions therapeutic measures must pursue, and the especial channels along which a modified system of hygiene must flow. The psychological studies must determine constructive ability and learning ability, imaginativeness, the type of memory, the power of concentration, motor coordination, and association, as well as the ability to follow directions and the degree of moral comprehension.

Educational investigation resolves itself into pedagogical tests in various branches studied in public schools, the careful analysis of the various elements entering into study, including the character of work performed with reference to the gradation at school, the necessity for private instruction, and the direction of education into fields untried but promising greater advantages to the mind. It is needless to say that the attitude of the child toward the school and the teacher frequently is of greater effect than a myopia or a chronic otitis that interferes with the channels of perception through which mental training is acquired.

It hardly appears necessary to stress the tremendous wastage of brain power from lack of its development. The accomplishments of a Laura Bridgeman, or a Helen Kellar, the reeducation of the crippled and handicapped, the renewed power that is developed following diseases of various types, indicate the tremendous gains that are possible through prolonged rational study and persistent and well directed efforts toward building up a body or mind that has suffered some unfortunate limitation. Such experiences as those with the deaf, the blind, the crippled, and the neurotic, indicate the benefits that might ensue were similar pains taken in the promotion of the health and welfare of the growing generation.

I have found the necessity for a careful social study of each particular child. By this I do not mean merely knowledge as to whether it comes from a home of wealth or of poverty, nor do I mean alone the degree of mentality of the parents. I refer particularly to the social relationships existing within the home, and those radiating into or out of the home. It is more helpful to know whether a child hates its father and why, than to know that it comes from a home of luxury and attends a high class private school. It is more advantageous to find the beginnings of habits of delinquency through social analysis than to accept the comment of the confessedly kind hearted parent who states that the child takes after a deceased uncle.

In short, to determine the character of mental hygiene to be instituted in any specific instance it is essential that the child and its various spheres of influence, whether centripetal or centrifugal, be explored. All the data thus acquired must be carefully weighed as evidence, balanced, and analyzed as a preliminary to determining upon a course of action. The need lies not in diagnosis, though it is essential for prognosis. The character of the prognosis, however, must depend upon knowledge of the possibilities of therapeusis, or prophylaxis. This is incontrovertibly true in the realm of physical and mental diseases, with all due regard for the necessary reservations due to human fallibility in judgment.

The study of pathology has given rise to most of the benefits that the world enjoys from hygiene. A knowledge of etiology must precede specific hygienic methods. There are, however, general principles of hygiene which are applicable to many diseases whose real cause has thus far failed of demonstration. This is equally true in the realm of mental hygiene, as it is in physical hygiene. What has been learned from the treatment of mental defectives, the handling of psychoneurotics and psychopaths, affords much of value for introduction into the lives of all children. Early attention to the slightest evidence of conditions common to mental disorders will accomplish far more than the application of indicated remedies after the disease has become acute. The purpose of the movement for the introduction of psychiatric clinics or the establishment of psychoeducational clinics, or the growth of ungraded classes throughout the country, is to discover mental disabilities to prevent further mental deterioration, and, constructively, to build up mental power to the maximum extent.

Mass study of this character presents numerous difficulties which hamper and delay or interfere with smooth progress. Individualization in treatment is obviously required. For this reason numerous group benefits will accrue from the more thorough study of individual children. Permit me to repeat: for the purpose of furthering mental hygiene, it is imperative that we give more attention to the psychological, educational, and social elements entering into child life, than has been our custom in the past. This does not mean any decrease in activities along the physical lines. In truth, more rather than less stress must be placed upon physical examinations, particularly of the nervous system, and the vast hazy territory of endocrinology. Not merely must defects and handicaps be noted and remedied, but tendencies toward physical disabilities should be sought and corrected.

The horizon of medicine has broadened. Just as the field of social service has extended so that social investigation is now an essential part of the highest form of medical practice, so the field of psychology and education are calling for a greater interest on the part of physicians. Character, conduct, and educability belong within the category of states claiming medical thought. What is required is a new point of view regarding human beings. We must think in terms of health and hygiene; but the application of these terms must embrace the physical, mental, and moral development of human beings who are entitled by virtue of their birth to the amplest opportunity for the highest development. In the beginning this work should be coincident with life and receive its greatest impetus during childhood. Mental hygiene during this wonderful era of childhood promises new rewards and benefits for the race. The beginnings, however, must be found in the study of individual children along all the lines suggested: the physical, psychological, educational, and social phases of child life.

264 West Seventy-third Street.

ELECTRONIC REACTIONS OF ABRAMS.

OVERT PHENOMENA.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

San Francisco, Cal.

Elsewhere[1] reference has been made to these reactions in detail. In our repeated references to the latter we have commented on the sensitivity of the human reflexes for demonstrating infinitesimal radioactivity, which is an inherent property of all matter. It is difficult to conceive of any mechanism* which is responsive to ethereal vibrations at a rate of 500 million million a second. Thus it is that the physicist recognizes only a limited number of bodies possessed of radioactivity, although he concedes that all elements are radioactive.

Recent reports from the Department of Agriculture show that old maxims bearing on farm practice are more reliable than deductions recruited from scientific data. These traditional maxims are based on the behavior of plants and animals which are more sensitive and consequently more responsive to external conditions than any instrument yet devised by man. In despair and in accordance with the foregoing a science of phenomena, "Phenology," is proposed. The physiological responses to infinitestimal atomic energy have merely escaped observation, thus making knowledge defective not so much for want of knowing as for want of looking. There is never a sensation from within which does not find its expression from without.

The writer has shown elsewhere[2] how the heart

*The writer has constructed an apparatus known as the Electroradiometer, which is essentially an electric balanced electroscope enabling him to differentiate radiant energy. Although practical, it does not attain the sensitivity of the human reflexes. It was the electroradiometer which enabled him to devise his oscilloclast, an apparatus by which major operations may be executed by aid of a definite vibratory rate secured from an electric circuit and from which absolutely no sensation is felt by the patient.

may be utilized for demonstrating and differentiating various forms of energy. Brief reference at this time will be made to new vasomotorial and muscular phenomena. Practically all diseases yield a definite physiological topography as shown in

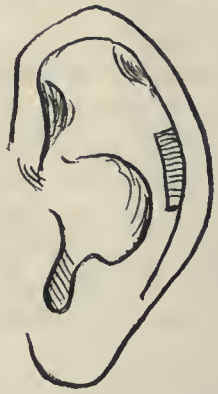


Fig. 1.—Area of localized hyperemia when tuberculous energy is conveyed to the navel. A more intense hyperemia is noted when the energy is applied to the *center of the forehead.* The area of hyperemia is supplanted by *pallor* when the end of the culture tube is applied at a point about 3 in. to the left of the navel.

"Iconography of the Electronic Reactions of Abrams," but at this time reference will be made only to tuberculosis. For the rationale of the phenomena, the reader is referred elsewhere.[1]

To objectify the following overt physiological reactions, the initial exaction is a modicum of patience.

General Exactions.—Practically any nontuberculous person of either sex (subject) may be used for the physiological reactions. The subject must be seated facing the geographical *West* in proximity to a window with the feet on a metal plate grounded by means of a wire to a faucet or radiator. This grounding may be effected without a plate by fastening a wire to the subject's leg and the other end to a faucet or radiator.* Preliminary investigations may be made with a culture tube of tubercle bacilli. The latter must be so grasped that the finger tips of the experimenter must not be pointed in the direction of the culture tube (to avoid the radioactive polarity issuing from the fingers). When the phenomenon is evident to the experimenter, he may conduct the energy through a conducting cord (preferably with aluminum electrodes, not in excess of 1 in. in diameter) from a suspected tuberculous lesion to the receptive area of the subject. Better results are achieved if the patient as well as the subject is grounded. Later, by employing a special ohmmeter, he may differentiate the energy thus

*Later investigations show better results when the reagent (subject) is insulated and not grounded. To

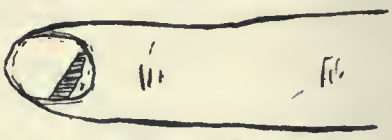

Fig. 2.—Area of pallor in the fingernail (preferably ring finger) in tuberculosis.

achieve the former, reagent stands on a rubber mat; if seated, feet on a rubber mat and chair on same or other insulating substance. Arms must be away from body and feet separated to prevent short-circuiting; a subject to be discussed in a future number of this Journal.

conveyed through the latter by noting that the physiological response is only at either 15 or 57 of the scale. Furthermore, he may be able by aid of the ohmmeter to measure the potentiality of the energy and thus note the progression or retrogression of

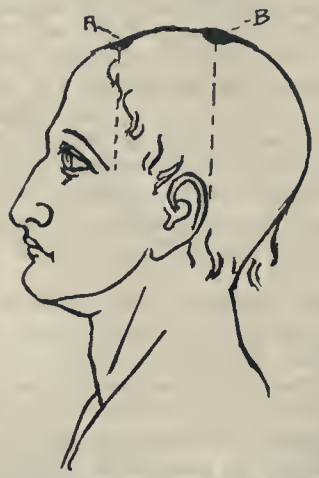

Fig. 3.—A—Receptive area to elicit the myoscopic reactions (center for muscular tonus); B, hypothetical centrum for atonicity.

the disease. The physiological reactions in question furnish the earliest evidence of tuberculosis and far exceed in value the conventional methods employed in diagnosis. With a pointed aluminum electrode the area of the lesion may be defined. Thus, when the electrode attains one side of the area, there is a response and so with other sides of the area which may be marked with a pencil. The reactions may be noted in artificial light which must be at some distance from the subject.

The writer has shown[2] how the patient may be utilized (without a subject) for diagnosis by aid of the electronic reactions and, in the same work, how the ear of a white rabbit may be employed for a like purpose.

Otoangioscopy.—Select a subject with a moderately red ear (a congested ear is of no value). Note that when the end of the culture tube is applied in

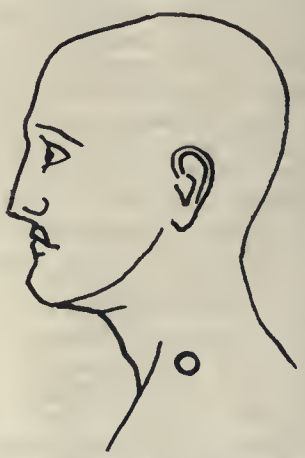

Fig. 4.—Circumscribed retraction of the skin from tuberculous energy conveyed to the area shown in Fig. 3A.

the region of the navel, there is an immediate response in the area shown in Fig. 1. The physiological response is an area of circumscribed hyperemia, and if any veins are present their engorgement is apparent. Most subjects can localize the

area by the burning sensation which persists for a variable period after the removal of the tube. The experiment with the same subject can be repeated only a few times owing to the persistence of the hyperemia.

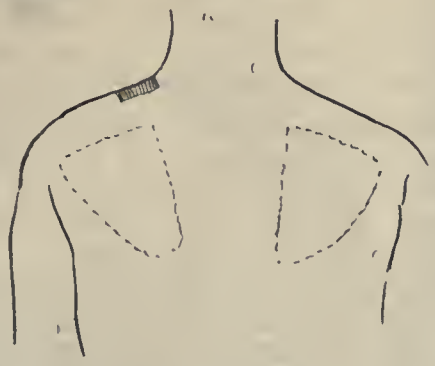

Fig. 5.—Suprascapular myoscopic reactions.

A better hyperemic response is achieved when the tube is placed in the *center of the forehead.*

Onychoscopy.—It is difficult to observe circumscribed areas of hyperemia in the nails so that observation must be limited to areas of pallor. If the end of the tube is applied to the subject at a point on a line with the navel and about 3 in. to the left of the latter, pallor will be noted at the area shown in Fig. 1. In the application of the energy to the receptive abdominal areas, it is unnecessary to remove the clothing, although better results are achieved when the tube approximates the skin.

Myoscopy. — Exactions (position, grounding, light, etc.) like the elicitation of the foregoing reactions. Thin individuals are alone adapted for the myoscopic reactions. The receptive zone* for the tuberculous energy in these reactions is the area A shown in Fig. 3, viz., at a point corresponding to the median line of the vertex, on a line drawn from the outer borders of the orbitæ.

Reaction of the Platysma Myoides.—When the end of the culture tube is placed at A, Fig. 3, a

*Abrams' heart and lung reflexes are universally recognized by stimulation of definite spinous processes as shown in "Spondylotherapy" and elsewhere. Stimulation of the area (Fig. 3A) will elicit these reflexes of greater amplitude and duration. If this area is struck with a plexor by aid of a pleximeter and the small veins of the hand or arm are noted, the veins in

Fig. 6.—Brachial myoscopic reactions.

question will be seen to contract. The writer assumes that this area (Fig. 3A) is the center for muscular tonicity. If an area corresponding to the center of the vertex (B, Fig. 3) is stimulated by concussion or sinusoidalization the veins become engorged. These centers may be utilized in treatment (cephalotherapy).

retraction of the skin ensues which is invariably in the same area (Fig. 4). This area may be identified after several observations.

The myoscopic like the vasomotorial reactions are easily exhausted. Pulsations and movements due to respiratory excursions are easily excluded.

Suprascapular and Brachial Reactions (Figs. 5 and 6).—The energy is conveyed to the same area (A, Fig. 3) for all myoscopic reactions. Note, however, that in these reactions there is no retraction of the skin, but a muscular wave (not unlike the fibrillation observed in muscular atrophy) pursuing the direction as shown in Figs. 5 and 6.

Addendum. — Various unsatisfactory theories have been suggested to explain the supposed miraculous power of dowsers: (1) That they guess at the position of what they are about to discover; (2) that a knowledge on the part of diviners of the locality and of its geology are sufficient; (3) that the power is an involuntary action resulting from a fixed idea.

Every man is an ideo-motor being and his idea is expressed in some kind of external motion. It is impossible to entertain an idea without participation of the whole body in harmony with it.

The dowser's method to find water is to grasp the limb of a twig (divining rod) firmly in each hand.

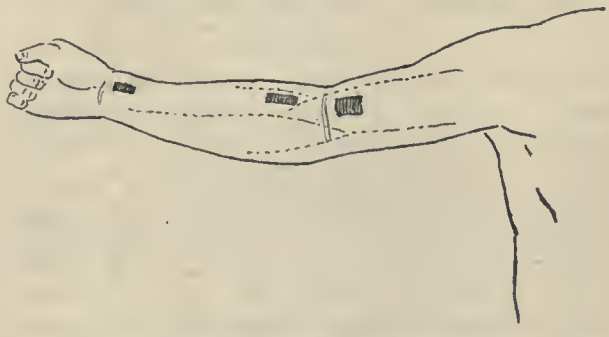

Fig. 7.—Areas of muscular reactions when the energy from water is conveyed to A, Fig. 3.

He holds the rod in front of him and proceeds slowly. When he arrives at running water, the twig jerks up and down, and not infrequently it twists around in the dowser's hand. Anyone can demonstrate by the following myoscopic reactions that the correct explanation of the dowser's method is involuntary muscular action independent of a preconceived idea. It must be recalled that there are reflexophilic individuals with exaggerated reflexes. With the latter the myoscopic reactions are accentuated.

The grounded subject faces the west with bare arms held in a semi-flexed position. Use a cord with electrodes. One electrode is fixed at A (Fig. 3), whereas the other electrode is brought into proximity with a large quantity of water in a bathtub. Note that the moment the electrode is over the water (knowledge of the subject to be excluded), a slight twitching is observed in the areas shown in Fig. 7. Note that when the water is agitated there is a decided muscular twitching, notably at the lower portion of the biceps.

The electric sensations of dowsers are muscular contractions and the latter are in direct proportion to the quantity of water and its depth. The dowser's reactions are evident only over running water.

PSYCHOANALYSIS OF THE HEART.

BY AURELIUS R. DE JANIS, M.D.,

BOSTON, MASS.

"IT is often a mistake on the part of the physician to inform his patient of the presence of organic disease of the heart. Such an announcement will only tend to militate against the best chosen remedies by depressing the patient's spirits, and thus lowering the vital energies. It is better to encourage; and allude to the heart only in an indirect manner."

The heart is one of the so-called involuntary muscles, and an organ supposed to be beyond the influence of the will, if not of the mental sphere. This view is not entirely correct, for we know that the action of the heart is often disturbed by merely centering upon its consciousness, and without any emotion or anxiety. For example, the physician can often induce palpitation and irregular pulsation by merely feeling the pulse. Such action is apparently brought on by the effort of attention even though there is no evidence of undue emotion.

The heart is an organ which is highly susceptible of emotional excitement and neither volition nor the coolest temperament will give immunity from this susceptibility. It has long been noticed that long-continued anxiety will lead to a feeble and slow action of the heart and at the same time render the organ irritable and liable to become excited under the slightest access of emotional feeling.

A sudden and painful mental shock has also been known to arrest the action of the heart, or to excite it to such a degree as even to injure its valves or their cordæ tendineæ. Furthermore, we often hear the phrase "died of a broken heart," and this is not purely figurative, because sudden death may undoubtedly be sometimes due to a ruptured heart caused by violent emotions. Terror or joy, when it suddenly seizes a person already overpowered by despair, may paralyze the heart. History tells us that the Roman matrons, after the battle of Cannæ, on seeing their sons, whom they supposed to have been killed, dropped dead on the spot.

Fear, which is the chronic form of fright, occasions a tremulous palpitation; rage also may produce precordial oppression, and is known even to have brought on an attack of angina pectoris. Excessive grief will cause functional disorder with deranged action of the valves, the patient becoming pale and anemic. It is a general rule that hope will excite and sustain the organ; despair and anxiety will depress it; and contentment and peace of mind will give it healthy action.

I am convinced that but few physicians realize the great importance of the relations of the brain with the heart; or even appreciate the connection between the soul and that center of physical life. We might even assert that as there is a corporeal heart (the life-giving center of the body) so there must be a spiritual heart, (the center of soul-life), Else, why is the word "heart" continually applied to the feelings, the impulses, and emotions?

It is further said, a man "has a heart" or "no heart," that such an emotion "comes from the heart or the head," thereby indicating that a one kind of feeling may come from the soul, and another from a more "calculating" center. And all the grand, noble, and loving impulses of our nature are said to come from the "heart," while the cold, unemotional, and "practical" acts are said to emanate from the brain.

It is a well-known fact to anatomists that animals possess the power to move and govern certain muscular organs and muscles, while man possessing the same muscular structures has no apparent influence on them. Our attention may well be attracted as to how far this influence extends to the heart; however, this is a problem, and this sympathy between the mind and the heart should not be overlooked, for a full appreciation of it may lead us in certain cases to form more correct diagnosis than could otherwise be made.

A physician may be treating the heart with medicines, when his efforts should be directed to a "diseased mind." It cannot be too strongly insisted upon that we should never lose sight of the psychological relations of the heart as well as its anatomical, physiological, and pathological history.

74 WESTLAND AVENUE.

Medicolegal Notes.

License to Practise—Neuropathy.—The Pennsylvania Superior Court holds that a person who is a graduate of the American College of Neuropathy and who describes himself as a doctor, may be convicted of practising medicine and surgery without a license, where he practises a system which is described as "A science of the healing art by which all diseased conditions of the body are restored to health by regulating the blood supply to the involved areas through the nerve mechanism, but exclusively by the physical manipulation around and above the affected parts of the human body." The court said that in order to practise medicine one need not cover the entire field of the science. If he devotes himself to a very restricted part of it, he may still be held to be practising medicine. There has been great specialization in the profession, and the purpose of the statutes seems to be to permit the practice of special methods of treatment including everything that strictly belongs to each, provided such practitioners have the required general knowledge of medicine: Commonwealth v. Jewelle, 199 Mass. 559; Commonwealth v. Zimmerman, 221 Mass. 184. "To rule out of the profession great physicians whose work is confined to consultation, the diagnosticians, who leave to others the details of the practice, and the administration of drugs, or the use of surgical instruments, would be to eliminate a very important branch of medical and surgical practice": People v. Allcutt, 189 N. Y. 517. The law is not concerned with the question whether Chiropractic or Neuropathy is as good or better than other systems of treatment, but it is concerned with the grave question that before any one shall undertake, no matter by what system, to diagnose, treat, operate upon, to prescribe or administer remedies or treatment for any physical or mental ailment or condition of another, for a fee or other consideration, he shall possess the learning and skill required by the statutes, produce a degree or diploma from a college meeting the requirements enumerated in the statute, and pass an examination before the State Board showing his competency.—Commonwealth v. Seibert, 69 Pa. Superior Court 271.

SPINOVENTRICULAR LAVAGE IN THE TREATMENT OF MENINGITIS.

WITH the exception of tuberculous meningitis, it would seem that spinoventricular lavage is indicated in many types of meningitis which clinically and bacteriologically are regarded as fatal, such as suppurating traumatic meningitis when surgical intemperance has failed; suppurative meningitis from middle-ear processes in which the mastoid operation and spinal injections of the colloidal metals or of antistreptococcic serum are often without avail; cerebrospinal meningitis which does not respond to serotherapy; and lastly, the purulent meningitides, due to the streptococcus, pneumococcus, or Eberth's bacillus, which arise as complications of general or local injections.

The technique of the lavage consists of two steps: ventricular puncture and lumbar puncture. In infants ventricular puncture is relatively easy; the needle is inserted at the external angle of the anterior fontanel in order to avoid the sinus which is median, and is then pushed in from above downward and from without inward. In adults puncture is to be preceded by trepanation. The opening in the skull and ventricular puncture can be made at either of two different points. Sicard, Roger, and Dambrin advise opening the cranium at about three centimeters above the middle of a line drawn from the inion to the base of the mastoid apophysis in order to reach the occipital horn of the ventricle; Bellin, Alvin, and Vernet select a point three centimeters above the external auditory canal, pushing the needle in a direction perpendicular to the surface of the side of the brain operated on because the temporal horn is only three centimeters below and easily reached by the needle. Lumbar puncture is done according to the usual technique and should be made first, thus avoiding sudden hernia of the brain, after which puncture of the ventricle is done through the opening in the skull. The needle used should be about fifteen centimeters long, and is pushed directly in to the extent of four centimeters.

The lavage is then begun, using a syringe having a capacity of 20 c.c. through either the needle in the ventricle or that in the spinal canal. A physiological salt solution or specific serum is used, the quantity varying according to circumstances from 100 to 400 c.c., and the lavage may be repeated if necessary. In meningitis with predominating cerebral symptoms, ascending lavage should be done in order to avoid diffusion of the bacteria, and inversely. One of the principal points of the technique is to inject the fluid slowly.

The results obtained so far have been rather encouraging when the types of meningitis requiring this treatment are taken into consideration, as they are always the most severe, and when we consider also the possible improvement in the technique yet to come. One serious objection to this therapeutic measure is that it would be ineffective when the case offered a walled-off collection resulting from fibrinopurulent adhesions occluding Magendie's and Luschha's trunks, resulting in a pyocephalus which cannot be reached by the solution; but some recent observers maintain that the occlusion may not be absolute and that a sufficiently thin fluid may get through. In such cases they advise an essay with ascending lavage administered with all due precaution.

THE GREATER DELICACY OF MALE INFANTS.

IT is a well established fact, but one which is perhaps not generally appreciated, that many more thousands of boy than girl babies die, although in most years a few thousand more boys than girls are born. The consequence is that in all countries, with the possible exception of lands to which immigration is large, the preponderance of the female sex is considerable and ever increasing. In Europe, on account of emigration and recently because of the war, the undue disproportion of the sexes constitutes a grave problem. A well known English physician, Dr. R. Murray Leslie, a few weeks ago made this disproportion in Great Britain the text for a homily on the dangers to which the large preponderance of women was subjecting the population, and he dwelt especially on this law, that while more boys are born than girls, a considerably larger number of boys die than of girls. According to the views of some authorities, the main reason is that male infants are more complex animals than female infants, and that man is of another type than woman. Woman's function physiologically is to be conservative, to maintain the race-type. Man's function is to vary that type in accordance with the varying environment of the race. He is therefore more directly in touch with environment and he tends to exaggerate all the influences, whether good or bad, that play upon him. It is obvious that in the earliest stages of infancy environment is all-important. If there is any factor in this environment that is inimical to life the boy baby responds to it more energetically than the girl baby; that is, he is more delicate. It therefore follows that any measures taken to save infants of

both sexes will save more boys than girls and so the solution of the problem is to bring baby culture up to the highest point of efficiency, and nature will adjust the balance of the sexes.

The steps to be taken to secure this result would seem to be that, first, the medical profession should be more concerned as to the best means of rearing infants, and especially of guarding them during the earliest days of life. Another thing greatly needed is that the education of midwives and nurses should be improved; and lastly, parents should be instructed, mothers in particular, in the scientific aspects of parenthood.

Educational work of this description in the poor localities of the big cities of Europe has thoroughly demonstrated its worth. In Paris, in Brussels, in Ghent, the "Gouttes de Lait" not only have been the means of saving a very large number of infant lives, but have overcome to a considerable extent the drawbacks of unsuitable environment, and children reared on these lines have grown into healthy men and women. In London and other British cities the outcome of similar measures has been equally satisfactory. If it is true that boy infants are more difficult to rear successfully than girl infants, it is evident that the solution of the difficulty lies in efficient baby culture and child welfare work. The assertion which has been made that the boy baby is more susceptible to his environment because he is a finer and more delicate type will not be accepted by everyone. The male type and female type differ in certain respects, but it is a difference rather than a definite superiority of one over the other type. Each type possesses its characteristics of superiority. With regard to the powers of vital resistance inherent in either sex, it is probably a misnomer to term the female the weaker sex. The female has quite as much, if not more tenacity of life, than the male. But, however this may be, it is certain that there never has been a time when the need for the conservation of child life and the rearing of a healthy, vigorous race has been so clearly apparent as it is at the present time, and any measures calculated to insure this result will be welcomed and adopted throughout the civilized world.

FATAL MOUSE TYPHUS IN A HUMAN SUBJECT.

THE Loeffler mouse-typhus bacillus is morphologically, culturally, and biologically akin to the paratyphus B from which it differs chiefly in its pathogenicity toward the mouse. Experiments many years ago appeared to show that mankind is immune to this organism. Later, however, it was realized that it could attack men, and mass infections have resulted from the consumption of contaminated flour, the flesh of sick horses, etc., the symptoms being those of gastroenteritis. At least seven fatalities have been recorded.

Staub, an assistant at the clinic of Professor Stahelin at Basle has reported a case in the *Schweizerische medizinische Wochenschrift* for February 5, 1920, i, 6. The patient, a man of 62, ate some potato which was covered with mouse poison in the shape of cultures of mouse-typhus bacillus intended to destroy these animals. He later complained of vertigo and prostration and vomited repeatedly. The physician found him asleep and when roused with difficulty he staggered, behaving exactly as if drunk. The pupils were extremely narrow. He was given coffee. Next day the pulse, previously good, became rapid and weak and digitalis was ordered. Constipation had set in from the first and castor oil was followed by persistent diarrhea. There was no fever. The patient arrived at the hospital on the third day of the disease and was somnolent, highly emaciated, prostrated, and cyanotic, the blood pressure being 90. The emaciation, cyanosis, thirst, rice-water discharges, and other symptoms were decidedly choleriform. The highest temperature was 37.3° C. (99.1° F.) in the axilla. There was no response to treatment and the fatal exit took place on the fourth day after swallowing the poison. Section showed marked congestion of the gastroenteric tract. Pure cultures from the blood would ordinarily have passed for the paratyphus B, but when tested on mice along with the culture used on the potato proved to be the *Bacillus typhi murium* of Loeffler.

Characteristic of the disease is the extremely brief incubation period of about ten hours, the severe watery diarrhea setting in on the third day, and the acute dehydration and absence of fever. In other words it mimics closely the choleriform type of paratyphus B infection, otherwise the form of cholera morbus due to that germ, the autopsy finds also agreeing with that affection. Commercial mouse poison should therefore be placed officially among substances dangerous to man.

THE CANCER PROBLEM.

THE *Journal de médecine et de chirurgie pratiques* for February 10, xci, 3, is devoted to papers on cancer and of this number one by Plicque is general in scope. The author gives incidentally a digest of two papers by Hartmann and Lumière on four leading factors in the cancer problem of which the first deals with chronic irritations. Thirty-four distinct types of chronic irritation have been isolated, most of them being familiar to the student of can- of these sources of irritation, as paraffin and especially the betel nut or rather the lime used to facilitate its mastication. The skin is interested in many of these sources of irritation as paraffin and especially soot and *x*-ray burns. Gallstones are the irritant in cancer of the gallbladder and ducts, subpreputial infection in cancer of the penis. In cancer of the breast the friction of the upper border of the corset is accused. The change of chronic ulcers of various kinds into malignancy is well enough known, this being ranked as the second of the casual factors. The third in order is the region of least resistance and here is placed scar cancer.

The fourth known or supposed causal factor is parasitism which naturally can cooperate with the preceding, although parasitism is more readily brought into connection with sarcoma than with carcinoma, and sarcomatous tissue suggests a reaction toward some form of parasite in that it resembles in many ways the tissue of tuberculous and syphilitic gummata. Epithelial tissue is much less prone to proliferate under the stimulus of infection although this does occur now and then. The author also discusses implantation and grafts in connection with the parasitic theory. The parasitic theory, he thinks, is the only one which holds out any hope of cure of cancer, hence it stimulates research, in the direction both of an antiparasitic treatment and of modifying the soil by mineralization and demineralization, for if the dietetic theory of cancer is sound it must rest on the possibility that certain substances in excess, like protein, act as favorable culture media while defect or excess of certain mineral matter tends to render the medium unfavorable. The benefit from irradiation also suggests the destruction or inhibition of growth of microorganisms.

This is an approach to the more rational constitutional theory which is, however, by no means dependent upon a belief in parasitism for its acceptance.

Is Essential Epilepsy Hereditary?

Hartenberg answered this question in the negative at a recent session of the Société de Médecine de Paris (*Le Presse Médicale*, xxviii, 6) In 80 cases investigated from this viewpoint, only three showed epilepsy in the ascendants. Since the disease is thus no source of reproach to the family, it need not be concealed. It is somehow acquired and is casual or accidental, and should not be regarded as incurable. In the discussion that followed Tellemer conceded the rarity of epilepsy in the patient's ascendants, but has found that if epileptics marry, their children seem tainted in some way. Laignel-Lavastine cited in addition to himself Pierre Marie, Babinski, and Comby, none of whom believed in the heredity of idiopathic epilepsy. This means that epilepsy is no autonomous disease but a syndrome. In some cases the accidental cause is apparent, as an infection is early childhood which sensibilizes the brain. Blind agreed with the other speakers, and he believes the Scandinavian laws forbidding the marriage of epileptics to be unjust. In closing Hartenberg agreed that epilepsy is a syndrome and that the term idiopathic epilepsy means nothing, although it is very handy to indicate the affection in an otherwise normal subject. It does not differ essentially from socalled symptomatic epilepsy in which some alleged cause is apparent. Cranial wounds and other individual factors can cause essential epilepsy as well as atypical forms by sensibilizing the brain.

Acetonuria of Fatigue.

The various familiar conditions under which acetonuria develops may be amplified by fatigue, according to Azzo Azzi in *La Riforma Medica* for November 8, 1919, xxxv, 45. The acetone bodies occur in normal urine in a concentration which amounts to 0.0136 gm. in 24 hours. In fatigue as studied in troops during a war footing this amount may increase to the figure of 2.5 gm. in 24 hours. The essential requirement to get such figures is unremitting activity without the least repose. When at last the subject favors himself and rests, the amount diminishes at the rate which would be anticipated. Forced marches supply the conditions which are calculated to produce acetonuria in excess. Of collateral phenomena observed the ammonia excretion was very irregular and the same was true of total acidity, but the excretion of ureic N in the most notable cases of forced march was notably diminished. The increase in the acetone bodies stands in relation to the sense of fatigue. How explain the increase in acetone bodies in fatigue? Is it a mere index of increased combustion? This cannot be answered offhand, but it is quite possible that these substances constitute in part the poison of fatigue and are neurotropic, causing the sensation of weariness —in other words, from this viewpoint the autointoxication of exhaustion is expressed by acetonuria. The author does not mention the fact that the sense of fatigue occurs without acetonuria, and that the latter does not develop in fatigue from brief intensive muscular activity. Most of our knowledge of experimental fatigue concerns the shorter, intensive efforts.

News of the Week.

Insane Asylum Under Investigation.—The New York State Hospital Commission, at its recent quarterly meeting held in New York City, instituted an investigation concerning the detention of the aged Brush sisters for ten years in the State Hospital for the Insane at Kings Park, L. I.

Milk Commission Advocated. — The passage of the milk commission bill, with power to regulate the price to the producer, distributer and consumer, is strongly advocated by Governor Alfred E. Smith of New York as necessary to protect the women and children of the State.

Legal Control of Glandular Products Urged.— At a session of the Section of Medicine of the New York State Medical Society, during the recent meeting held in New York City, Dr. S. W. Bandler suggested the wisdom of legal control of the sale of glandular products for life extension or other purposes. He urged the appointment of a committee of fourteen physicians to take the initiative in the matter of the prevention, by legislation, of the sale of such products by druggists without a physician's prescription.

Medical College Alumni Association Organized. —Five hundred physicians, alumni of the New York University and Bellevue Hospital Medical College, met in that institution March 24 and organized an alumni association. A motion to create a legislative committee was finally adopted, after considerable discussion and opposition. Dr. Robert J. Carlyle was elected President, Dr. Robert J. Wilson, Vice-President; Dr. C. J. Lyson, Secretary, and Dr. Godfrey Fisk, Treasurer.

Smallpox in Jersey.—Nineteen cases of smallpox have been reported in Belleville, N. J. All public

school pupils are being vaccinated, and churches, "movie" houses, and all public halls have been ordered closed.

Soldiers' and Sailors' Home Investigated.—Charges of cruelty to inmates called forth an investigation of the Soldiers' and Sailors' Home at Bath, N. Y. Dr. Robert P. Bush, President of the Board of Trustees of the institution, made a general denial of the charges of mismanagement and cruelty to the inmates. Dr. Raymond Hills, house physician, also denied charges of mismanagement. Lieut. Governor Walker, who conducted the investigation, announced that a decision wuold be made two weeks later, if no further direct evidence of import developed.

Fifty Thousand to Post-Graduate.—Announcement has been made by the New York Post-Graduate Medical School and Hospital endowment fund committee of the receipt of fifty thousand dollars from James C. Brady. This is an encouraging start for the two-million-dollar drive launched by the committee on March 30.

Doctors Advocate Universal Military Training.—Thirty prominent physicians have sent a letter to the members of Congress urging the adoption of universal military training. It is contended that "universal training would be of inestimable value as a means of determining the proportion of young men physically fit or unfit and the underlying causes contributing to both conditions, aside from its many other desirable features."

Scarlet Fever at Brown University.—In consequence of a sudden outbreak of scarlet fever at Brown University, Providence, R. I., it was decided to close the university at once. This was done March 25, after a conference by President Faunce with the Commarian Club and Dr. Charles V. Chapin, Superintendent of Health of Providence. Warnings were sent to health authorities of towns and cities to which the students might go to be on the watch in the homes of the students for signs of scarlet fever.

Healthiest Town in the Country.—According to report Wassaic,' Dutchess County, N. Y., holds the banner for health. Although the township is nearly two hundred years old it has never supported a cemetery within its bounds and has no resident physician. It is not stated that there is any cause-and-effect relationship here, nor is the inference necessarily to be drawn that the inhabitants of nearly two hundred years ago are still alive.

Funds Needed for Orthopedic Hospital.—An appeal has been made by Robert S. Brewster, President of the New York Orthopedic Dispensary and Hospital, 420 East Fifty-Ninth Street, for funds with which to continue the work of the institution. The expenditures this year will amount to $220,000, an increase of $37,000.

Sugar Shortage and Drug Addiction.—Dr. S. Dana Hubbard, Director of the Bureau of Public Health Education of the Health Department, New York City, is credited with the theory that there may be a relationship between sugar shortage and increase in drug addiction. In 1919, he pointed out, the consumption of sugar in the United States was 5,200,000 tons, an increase of about 1,000,000 tons over 1918, and a per capita approaching 100 pounds. Should this not continue, and should the public be deprived of chocolates, soft drinks, and other sweets, drug addiction will follow the deprivation, according to Dr. Hubbard, who therefore urges the conservation of sugar.

Proposed Medical Center for Southwest.—The Board of Directors of the Baptist Memorial Sanatorium, Dallas, Texas, is working out plans, according to M. H. Wolfe, Finance Chairman, to make Dallas the medical center of the Southwest by the building and equipment of a hospital and medical college equal to any of the larger institutions of the country. Funds are being raised for this purpose. The Baptist Memorial Sanatorium, Baylor College of Medicine, Baylor College of Dentistry, Baylor College of Pharmacy, and the Baptist Training School for Nurses are considered as an adequate basis upon which to elaborate such a medical center.

Fifty Per Cent. Raise in Fees in Chicago.—At a recent meeting of the council of the Chicago Medical Society a new scale of fees was adopted, some of which are as follows: House visits, former maximum 5, now $15; night visits, formerly $3 to $10, now $10 to $50; operations involving fractured ribs, formerly $25 to $50, now $50 to $500; toe amputations, formerly $15 to $50, now $50 to $200; major operations will range from $200 to $10,000. The scale will be flexible, it is held, always governed by the patient's ability to pay.

Compulsory Filing of Birth Returns.—Senator George T. Gorton of Pawtucket, R. I., recently introduced an amendment to the present Rhode Island law, which, if passed, will require physicians of the State to file birth returns with city and town clerks within four days, and which will require the clerks to make monthly instead of annual returns to the State Board of Health of their birth and death registrations. The proposed amendment is designed to assist the State Board of Health in obtaining prompt birth returns from physicians. The penalty for violation of the proposed amended law is a fine not exceeding fifty dollars, nor less than ten dollars. The penalty under the present law is a fine of not less than two nor more than ten dollars.

American Urological Association Meets.—The American Urological Association held its seventeenth annual meeting at the Hotel Commodore, New York City, March 23, 24 and 25, under the presidency of Dr. Arthur L. Chute of Boston. The following officers were elected for the ensuing year: *President*, Dr. W. F. Braasch of Rochester, Minn.; *Vice-President*, Dr. H. G. Bugbee of New York City; *Secretary*, Dr. Henry L. Sanford of Cleveland, Ohio (re-elected); *Treasurer*, Dr. James A. Gardner of Buffalo (re-elected). Montreal, Canada, was selected as the place of meeting for the next session.

New York Association for Medical Education.—The annual meeting of the corporate members of the New York Association for Medical Education was held at the New York Academy of Medicine March 12, under the presidency of Dr. Wendell C. Phillips. In his formal address Dr. Phillips emphasized certain features of the work of the organization. The committee, among other things, has undertaken to establish standards to be recommended as guides in the preparation of graduate courses in the various specialties, and, further, to induce some of our institutions to offer such courses of instruction to eligible medical students. It is

intended to issue a series of bulletins announcing to the profession these opportunities and facilities for graduate study. The first bulletin will probably deal with Ophthalmology and Oto-Laryngology, since plans are most nearly perfected in those subjects, but other bulletins will follow as rapidly as the material can be brought into shape.

Medical Missionaries Needed. — The Interchurch World Movement is making a plea for 655 medical missionaries for work in 1920, and for 1,831 during the five year period of the Interchurch Movement. The sick, blind and defective, it is held, hamper progress in non-Christian countries. In Africa and the East, there is a vast army of defectives—most of them needlessly so, it is believed—in China there are a million blind and at least 400,000 deaf; in India there are half a million blind, and in Cairo five per cent. of the population is said to be physically defective, usually blind or half blind. Even the natives of the African jungle are for the most part poorly nourished and physically below par.

Junior Red Cross Aids Children in War Stricken Countries. — School children in this country, through the Junior Red Cross, are feeding more than 3,000 Belgian school children at the school canteens established by the Red Cross. Thirty-two of these canteens are being operated. A free school is conducted at Roulers where 200 destitute children are being educated and cared for. Winter colonies have been established in Brittany and the south of France for children of the devastated regions. In Italy 500 children are being cared for and schools have been established in the Balkan countries. These and many other activities in aid of the children made destitute by war are being carried on by the Junior Red Cross.

Activities of War Relief Organizations.—During the past week the various agencies engaged in war relief acknowledged receipt of donations amounting to $73,810. The Fatherless Children of France, Inc., 11 West Forty-sixth Street, received $26,578 and reports the total fund at $1,147,864. The Central Committee for the Relief of Jews Suffering Through the War, 51 Chambers Street, reports $42,156. The American Jugo-Slav Relief, 511 Fifth Avenue, received $5,076, making its total $358,369.

Relief for Serbian Children.—The Serbian Child Welfare Association of America, 19 West Forty-fourth Street, announces the shipment to Serbia for destitute children of $10,000 worth of clothing and food supplies, contributed by the Foreign Mission Board of the Methodist Episcopal Church, through Bishop William Burt of Buffalo.

High Cost of Living Penetrates Wilds of Massachusetts.—A physician of the Bay State makes the following frank statement to his clientèle: "Owing to the extreme high cost of drugs and medicine I will hereafter be obliged to make a charge for all medicines furnished by myself and also all unsettled accounts over three months will bear interest at the rate of 6 per cent."

American Proctologic Society Meeting. — The twenty-first annual meeting of the American Proctologic Society will be held at Memphis, Tenn., April 22 and 23, under the presidency of Dr. Collier F. Martin of Philadelphia. Dr. Ralph W. Jackson of Fall River, Mass., is Secretary. The scientific sessions will be held at the Hotel Gayoso, and clinics will be held at the Memphis General Hospital, the Baptist Memorial Hospital and the University of Tennessee.

Military Surgeons to Meet.—The twenty-eighth annual meeting of The Association of Military Surgeons of the United States will be held at New Orleans, April 22 to 24 inclusive, with headquarters at the Hotel Grunewald. The sessions are open to the medical profession at large. Colonel James Robb Church, Army Medical Museum, Washington, D. C., is Secretary of the Association.

United States Civil Service Examinations.—Open competitive examinations are announced by the Civil Service Commission for Bacteriologist and Junior Bacteriologist, and for Inspector, Antinarcotic Act. Application blanks (Form 1312) and information regarding time and place may be obtained from the Civil Service Commission, Washington, D. C., or from the Secretary of one's local Civil Service Board.

Foot Clinics.—During the past year 11,000 persons were treated at Foot Clinics, New York City, an organization which gives free foot treatment to the poor. A bazaar was recently held to raise funds for carrying on the work.

Vaccination Fee Increase.—The Town Council of East Providence (R. I.) recently received a request through the health officer, for an increase in the amount paid for vaccinations. The price is fixed by ordinance. The Council took the matter under advisement.

Anesthesia Research Society.—The annual convention of this society will be held at Pittsburgh the week of October 4, this meeting to be in conjunction with that of the Interstate Anesthetists' Association and the Pennsylvania Medical Society. It is possible that the Western Pennsylvania Dental Association also will join in the meeting. The Governors have voted $200 to be apportioned in prizes for the best papers on research in anesthesia, such papers to be read at the national meeting. This offer is open to all students, surgical, medical, and dental practitioners in the United States. A committee of three has been appointed to prepare forms for a uniform anesthesia chart. The committee consists of Dr. A. F. Erdman of Brooklyn, Dr. A. H. Miller of Providence, and Dr. E. I. McKesson of Toledo. The society will also prepare and publish at the earliest moment possible a monograph on the best practices in anesthesia in obstetrics.

Lack of Window Glass Spreads Epidemics.—According to Lieutenant James H. Becker, Relief Administrator of the American Joint Distribution Committee for Jewish War Relief, the lack of window glass is responsible for the spread of typhus fever, tuberculosis, and other contagious diseases in Central Europe. The windows are closed with mud, shutting out light and fresh air in the effort to exclude the cold. Shortage of buildings causes overcrowding in these poorly ventilated quarters.

Lake Keuka Medical and Surgical Association to Meet.—The twenty-first annual meeting of the Lake Keuka Medical and Surgical Association will be held at Keuka College, Keuka Park, N. Y., July

29 and 30. This association, which comprises twenty-one counties of western New York, is peculiar in that it has no membership in the sense that most organizations have, but the meeting is open to all licensed practitioners of medicine. The controlling body consists of an executive committee appointed at the time of each annual meeting from among those in attendance from the various counties. There are no dues except a small fee for incidental expenses, which is paid by those who attend. Dr. E. Carlton Foster of Penn Yan, N. Y., is the Secretary.

Jubilee Dinner for Fifty-Year Practitioners.—A dinner was recently given in Kansas City in honor of the following physicians who have passed the half-century mark in the practice of medicine: Dr. John S. Mott, Dr. Jefferson Davis Griffith, Dr. J. C. Rogers, and Dr. John Wilson. Dr. John F. Binnie was toastmaster.

Community Nurses in Illinois.—At a recent conference between Dr. C. St. Clair Drake, State Director of Public Health for Illinois, and Miss Helen Fox of Washington, Superintendent of the Public Health Nursing Service of the Red Cross, it was decided that every community in Illinois having a population of more than 5000 will have a community nurse.

Dr. Max Mailhouse, for twenty years clinical professor of neurology in the Yale Medical School, has resigned, and his resignation has been accepted by the Yale Corporation, with an expression of appreciation of his long service.

Dr. Joseph M. Merchant, the oldest living graduate of Bowdoin College, Me., observed his eighty-sixth birthday at his home in Warren, R. I., March 15. He was graduated from Bowdoin in 1858.

Harrower Prize.—Cash prizes amounting to $500 are offered to members of the medical profession (and to medical students) by Dr. Henry R. Harrower of The Harrower Laboratory, Glendale, Cal., for a series of essays on the internal secretions. There will be five cash prizes: First, $250; second, $100; third, $75; fourth, $50, and fifth, $25. Any subject directly pertaining to the practical and clinical aspects of the internal secretions may be selected. It is suggested that the essays be directed at one special phase of the subject and not generalized too much. It is especially desired to direct attention and emphasis to three important points bearing on the character of the prize essays: (a) The importance of the endocrine glands in *every-day medicine.* (b) The closeness of their physiological and clinical relations. (c) The advances of organotherapy in general practice. Applications must be received before July 1, 1920, and the contest will close August 15, 1920. It is hoped that the awards may be completed and the prizes distributed in October, 1920.

Charitable Bequests.—Appraisal of the estate of the late James A. Scrymser of New York City recently filed shows that the residuary estate of $2,423,784, which was bequeathed for life to his wife, Mrs. Mary A. Scrymser, upon her death will be divided equally between St. Luke's Hospital and the American Red Cross.

Obituary Notes.—Dr. Edwin B. Reed of Asbury Park, N. J., died of cardiac disease February 2. He was graduated from Jefferson Medical College, Philadelphia, in 1884.

Dr. Julius Goldsmith of New York City, died March 10. He was graduated from the Eclectic Medical College of the City of New York in 1905.

Dr. Justin A. Walling of Milbridge, Me., died March 2, at the age of sixty-two. He was graduated from the Medical School of Maine in 1882.

Dr. Lucy L. Wendover of Springfield, Mass., died March 4. She was graduated from the Medical Department of the University of Michigan, and had practised in Springfield for twenty-six years.

Dr. Frank Fletcher Carr of Holden, Mass., died suddenly from cardiac disease March 7. He was graduated from the Medical School of Harvard University in 1893.

Dr. Joseph A. Gendron of Ware, Mass., died March 7 at the age of fifty-nine. He was graduated from Victoria University Medical Department, Toronto, Canada, in 1888. For a number of years Dr. Gendron was chairman of the Ware Board of Health.

Dr. Kenneth A. J. Mackenzie, dean of the Medical Department of the University of Oregon, died at his home in Portland, March 15, at the age of sixty. He was graduated from McGill University in 1881, and had practiced in Portland since 1882. Dr. Mackenzie was Professor of the Theory and Practice of Medicine at the University of Oregon from 1887 to 1907, and latterly Professor of Clinical and Operative Surgery. He was a fellow of the American Medical Association, the American Surgical Association, and the American College of Surgeons.

Dr. H. Murray Loewenthal of Brooklyn, N. Y., died March 13, at the age of forty-seven. He was graduated from the College of Physicians and Surgeons, Baltimore, Md., in 1892.

Dr. Ellen B. Ferguson, for many years a practising physician in Salt Lake City, Utah, died at Whitestone, L. I., March 15. In 1896 Dr. Ferguson was one of Utah's delegates to the Democratic National Convention.

Dr. Frederick J. Leviseur of New York City died March 19, at the age of sixty. He was graduated from the University of Göttingen, Germany, in 1884, specializing in dermatology. He was chief clinician in dermatology at Mt. Sinai Hospital and consulting physician in dermatology to the Montefiore Home and Hebrew Orphan Asylum.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, March 19, 1920.

Insurance Act Changed. — The main object of the Insurance Bill or partial revision of that bill introduced by Dr. Addison, the Minister of Health, into the House of Commons on March 11, last, was to provide for an increase in the rates of benefits under the present acts, in view of the fall in the value of money. The normal rate of sickness benefit is increased from 10/ to 15/ a week in the case of men, and from 7/6 to 12/ a week in the case of women, for the full period of twenty-six weeks; the rate of disablement benefit from 5/ to 7/6 a week for both men and women, and the amount of maternity benefit from 30/ to

40/. The bill does not interfere in any way with the fundamental principles of the National Insurance Act of 1911, which are that the cost of the benefits should be met out of compulsory weekly contributions by workers and their employers, together with a grant from the Exchequer. In order to provide for the increased benefits the joint weekly contribution is to be raised from seven pence to ten pence in the case of men, and from six pence to nine pence in the case of women, and in each case two pence of the increase is to be borne by the employer and one penny by the worker. The proportion of the cost of benefits to be contributed by the State is to be two-ninths in the case of the men as at present, and two-ninths, instead of the present fourth, in the case of women, with an additional Exchequer contribution toward the cost of women's benefits in the form of an increase in the existing Women's Equalization Fund.

An important proposal of the Government is that, except in the case of Ireland, sanatorium benefit shall be discontinued. The bill empowers the Minister of Health to make regulations providing for the disposal of any surplus standing to the credit of the sanatorium benefit fund of an insurance committee, after discharging all liabilities or for meeting any deficit in the fund. Regulations are also to be made to govern the disposal by insurance committee of registers, records or other documents relating to the administration of sanatorium benefit or to persons who have been in receipt of it. The expression "medical treatment and attendance" is to be held to include treatment and attendance in respect of tuberculosis. It is understood to be the intention of the Ministry of Health to deal with the question of tuberculosis treatment as a whole, and to this may be attributed the proposal to remove sanatorium benefit from the Act. Various amendments of the financial provisions of the Act of 1911 are proposed. For example, the sum to be retained by the Minister of Health out of each weekly contribution is increased in the case of men to two pence and one-third of a penny, and in the case of women to one penny and eleven-twelfths of a penny. In consequence of the present general increase in the cost of medical service, the bill provides for an increased contribution from insurance funds toward the cost of medical benefit, and fixes the total charge upon those funds at 9/6 per insured person per annum for medical benefit, including drugs as well as attendance, and a further sum for this purpose will be provided in the shape of a special grant out of public funds. As mentioned in a previous letter dealing with the Insurance Act, arbitration was decided upon to arrange the rate of capitation fee which should be paid to medical men working under the Act. The arbitrators, issued on Friday, March 5, the following award: That having heard and considered the statements of facts and arguments submitted to them, do hereby award, determine and advise that the capitation fee per insured person per annum should be eleven shillings. Although a considerable number of the medical men involved protested that eleven shillings was insufficient, and while there will be some disappointment, it is probable that the result of the arbitration will be accepted without bickering. It must be taken into account that the settlement is only temporary. In order to press their claims with greater force it is essential that the medical profession should not only show a united front but should possess a satisfactory defence fund.

The Nation's Health.—Supporting a supplementary vote in respect of the Ministry of Health in the House of Commons recently, Dr. Addison defended expenditure which had been incurred for precautions at the ports against the introduction of disease, and said that the screen which had been kept round Great Britain had been well justified. Expenditure on child welfare was very proper. This year 400 additional child welfare centers had been opened and we hope to open a great many more next year. They had extended midwifery service for a population of 200,000, and fifty maternity homes had been established. Infant mortality was considerably the lowest on record. It was now eighty-nine, which was eight points lower than in the two previous years, but it ought to be fifty. With regard to national insurance, the standard that ought to be maintained was to get for the insured person as good treatment as a medical man gave to his ordinary private patients. The new medical benefit regulations aimed at improved conditions. As a part of the scheme they were appointing a number of referees and consultants to whom cases might be sent when further advice was desirable.

Women Surgeons.—Yet another new departure has been made. Women physicians have been in existence for a considerable time, and some of the British medical degrees and qualifications are open to them. But a woman surgeon is a rara avis indeed, and the College of Surgeons has been closed tight against the entrance of females. However, the old order of things is passing away not gradually but with celerity, and one by one the forts of masculine privilege are being stormed by women and captured. The Royal College of Surgeons of Edinburgh has resolved to admit women to the Fellowship of the College on the same conditions as men. There seems no particular reason why, if we have women doctors, we should not have women surgeons. It would be no innovation either, as there are said to be many records of women practising as surgeons in medieval times.

Indian Medical Research.—The Secretary of State for India has succeeded in borrowing Dr. E. H. Starling, Jodrell Professor of Physiology at University College, London, whose services are needed to draw up a report before the hot weather sets in on the possible creation of an All-India Institute for Medical Research. Professor Starling will sail at once and will be absent from England for about three months.

Memorial to the Late Sir William Osler in Oxford.—The Vice-Chancellor of Oxford University presided at a public meeting held on March 6, to promote a memorial to the late Sir William Osler. The Vice-Chancellor said that they had met to show the respect and affection that was felt for their late Regius Professor, not only by the University of Oxford, but by the London, and

other universities and other continents. His name would always be associated not merely with the history of the chair he occupied, but with its actual existence by reason of the generous benefaction, of which he thought he was the first to hear from Sir William Osler himself. Whether it would be associated by name with the future history of the School of Medicine in Oxford would depend largely on the result of that meeting. Sir Clifford Allbutt proposed a resolution to the effect that the distinguished services of Sir William Osler were deserving of a permanent memorial in Oxford. Sir William Church proposed "that in view of the intimate association of Sir William Osler's life work with the study of the origin and prevention of disease, the most appropriate form of memorial would be an Osler Institute of General Pathology and Preventive Medicine." Professor Thomson, who seconded, said a memorial of the kind suggested typified the career of the man. Sir William began life by studying the causes of disease, and ended his life as the ardent advocate of the means for preventing disease. The one depended on the other, and in this proposed institution they would typify that intimate and close association. The Home Secretary, Professor Gunn, intimated that he had already entered into communication with friends of the late Professor Osler in America, and a provisional committee had been formed consisting of Professor Welch, John Hopkins University, Baltimore; Harvey Cushing, Harvard University, Billings, Chicago, Dr. Butler, President of Columbia University, and Dr. Walter James, New York, to cooperate with the committee, and it was hoped a similar arrangement would be made in Canada.

Plague on a Japanese Liner.—The Ministry of Health has announced recently that the case of plague occurring on the S. S. *Alpo Maru* in the port of London, announced on Feb. 19, was followed by a further fatal case among the crew while the vessel was in port. The ship was disinfected as far as practicable and left the port of London on March 6.

Obituary.—Dr. Samuel West died in London, on March 2, at the age of 72. He was educated at Oxford University and St. Bartholomew's Hospital, London, taking the degree of medicine of Oxford and the F. R. C. P., London. Dr. West became assistant physician to St. Bartholomew's Hospital in 1887, and full physician seventeen years later, and at the same time was physician to the Royal Free Hospital and to the Victoria Park Chest Hospital. Dr. West was examiner at the Universities of Oxford, Cambridge, London and Birmingham, and at the Conjoint Board. He will be perhaps best remembered for his labors to assist the dependents of impecunious members of the profession by means of the Royal Medical Benevolent Fund. During the war Dr. West initiated the Special War Emergency Fund, and became chairman of the executive committee of the Professional Classes War Relief Council. He was not a voluminous writer but all he wrote was well worth reading, because of its exact knowledge. His "Diseases of the Organs of Respiration" went through several editions, as also his practical guide, "How to Examine the Chest."

2. The Specific Treatment of Hay Fever. Francis M. Rackemann.
3. A Case of Tumor of the Sacrum. Joel E. Goldthwait.

2. The Specific Treatment of Hay Fever.—Francis M. Rackemann presents a study of ninety-one cases of hay fever treated by means of repeated injections of the specific pollen which caused the disease. This method is now a well established therapeutic procedure, yielding results which are on the whole very satisfactory. These results, however, are often irregular and by no means perfect. The purpose of the writer is not only to detail the results in his own cases, but by studying the irregularity in the results to try to throw light on the mechanism of the disease. The results of treating the ninety-one cases of fall (ragweed) hay fever are as follows: Nearly 9 per cent. of patients are entirely freed of their symptoms; another 62 per cent. are considerably relieved. Of the remaining 28 per cent., about one-third showed no relief at all. These results were determined by a personal communication to each patient four to six weeks after the ragweed season. Because this final report was not obtained, nineteen other cases are not included. The best results are apparently obtained with a moderate amount of specific treatment since in these cases even after considerable preparation the tolerance for ragweed pollen extract still remains at a very low level. Systemic reactions occur after two per cent. of individual injections and are not always due to an overdose. In view of the fact that so few of the postulates of experimental anaphylaxis hold good for hay fever, it is probable that hay fever depends upon a mechanism which is not "anaphylactic" but which is perhaps closely associated with that of drug idiosyncrasies.

1. Practical Application of Methods of Standardization of the Hospital.—George Gray Ward reviews briefly some of the afforts made along the line of the standardization of hospitals, giving the requirements of the minimum standard as laid down by the American College of Surgeons, and discusses the provision of the Board of Governors of the Woman's Hospital, New York, for a reorganization of the service in line with this movement. He emphasizes the point that as soon as the trustees of hospitals and the public at large appreciate that at present they have no accurate knowledge of the character of the work being done, and that they cannot have such knowledge unless a systematic study of end results is carried out on the lines followed in large industrial plants where the production sheet shows facts, not suppositions, they will demand such a public accounting, and if it falls short of what they have a right to expect of the hospital and its staff, they will insist upon the necessary reorganization to make that institution efficient.

5. The Reconstruction of Workmen After Injury.—Prescott Le Breton holds that three things are needed in the city to provide for the large class of workmen rendered defective through injury, and these should be under the supervision of the city and under the department of public welfare. He states these requirements as: 1. An employment bureau for the partially disabled, where such men can apply and leave their names,

and where employers can find men as they need them. 2. A Zander treatment room in connection with some large hospital or dispensary, where the work for the man can be directed by surgeons. In this room, which should be in charge of a Swedish masseur, there should be a sufficient number of simple exercising machines, such as were used during the war. By means of massage, and voluntary motions, many cases can be materially improved. This end treatment is so often neglected in practice, but is effective in many cases in relieving poor circulation, strengthening muscles, loosening stiff joints, and overcoming pain and soreness. 3. The most important item is the opportunity of learning some simple trade whereby in a few months such men can earn enough to support their families. The most practical place for this is in one of the technical schools where industrial trades are taught.

3. Gonorrheal Infection in Childhood.—P. Brooke Bland considers gonorrhea one of the most troublesome and serious infections in infancy and childhood. This malady is much more frequent in the female than in the male, but fortunately widespread infection in little girls is far less common than in women who have entered the active menstrual life or those in early adolescence. Deep pelvic involvement in children, therefore, is not the rule, although destructive peritonitis before the advent of menstruation does sometimes occur. This favorable tendency of the disease to localization is overbalanced by its vicious determination to persist and to develop into a family or institutional contamination, as seen in a general infection of a family group, in girls' orphanages, or in the pediatric wards of hospitals. In the great majority of cases of vulvovaginitis—as gonorrheal infection in female children has come to be called—the infection is indirect and the organisms are conveyed to the children through ignorance and carelessness. Direct infection by coitus with the infected male adult is comparatively rare, as likewise is parturient infection. The majority of cases occur between the second and tenth years. The constitutional reaction to the disease is not commonly observed by the physician and the general systemic symptoms, as a rule, have disappeared when the patient is presented for treatment. The first complaint is of itching, which is quite constant day and night, and may be so pronounced as to interfere with the child's rest. This itching, and the rubbing incident thereto, may be the first signs to arouse the parents' suspicion of trouble. The child also complains of a burning or stinging sensation which is decidedly aggravated during urination, causing the child to refrain from emptying the bladder as long as possible. If marked urethral involvement complicates the trouble, the dysuria becomes more marked. Shortly after the onset of the disease the discharge appears, at first thin and ichorous, later assuming the typical thick yellow or yellowish-green profuse gonorrheal type, in the still later stages becoming mucoid, creamy or watery. The duration of vulvovaginitis is as varied as its course. Many cases respond fairly promptly to treatment and tend to a favorable result; in others, despite every measure, the trouble persists and recurs. Prognosis should always be guarded. Under the head of treatment the writer emphasizes the importance of preventive measures, especially in institutions for girls, babies' hospitals and pediatric wards of general hospitals. The active treatment should begin with the use of simple non-irritating solutions and applications, care being taken to cause as little fright and pain as possible for the first few treatments. Bland advocates copious cleansing of the vulva and vagina for two or three days with simple warm water. This is accomplished through a number fourteen soft rubber catheter. After gaining the confidence of the child, Lugol's solution of iodine in warm water is employed; beginning with a very weak solution, usually one quarter of a teaspoonful to two quarts of warm water, or approximately one quarter of one per cent. This is gradually increased to one per cent. The vulva is first thoroughly cleansed with this preparation, after which the catheter is introduced into the vagina and this canal is thoroughly flushed. The irrigation is carried out morning and evening and continued for at least three or four weeks. In addition, once daily a twenty-five per cent. solution of argyrol is instilled into the vaginal canal. At the same time the vulva is painted with this material and a cotton pad moistened with twenty-five per cent. argyrol is placed in contact with the labia and vestibule. After a month or six weeks the irrigation is used once daily, but the application is carried out daily. This treatment is continued until four successive negative smears are returned and also until the complement fixation test is negative.

4. Blood Transfusion in Modern Therapeutics.—George I. Miller holds that the transfusion of blood in some cases is as absolute a specific as is quinine, digitalis or salvarsan. Performed in a proper case and at the proper time, transfusion is an immediate life-saving therapeutic remedy, unequaled by any drug, including the specific remedies. A patient who is unconscious from gas poisoning, or from acute loss of blood from any cause, can often be saved by the prompt transfusion of blood, and not always by saline or drugs. The writer cites several cases with different pathological lesions in which transfusion was done. In hemorrhagic diseases of the newborn he found that transfusion checked the bleeding and restored the blood which had been lost. Anemia resulting from profuse and prolonged menstruation in virgins may be remedied by transfusion when the usual remedies have failed to check the bleeding. In patients who suffer from blood dyscrasia, as in hemophilia, transfusion of whole blood renders the coagulation time approximately normal and checks the bleeding. In purpura hemorrhagica transfusion is an exceedingly valuable remedy. The writer feels certain that in pernicious anemia life can be prolonged by transfusion, but a complete recovery cannot be promised. The successful use of transfusion in these and other affections leads Bland to believe that it is a therapeutic remedy of the greatest value when employed in the early stages of the various conditions.
